TMF	tailings management facility

1.0 INTRODUCTION

The Lynn Lake Gold Project (LLGP; or "the Project") consists of two primary deposit sites, which are both located near Lynn Lake, Manitoba: the 'Gordon' site and the 'MacLellan' site. Alamos Gold Inc. (Alamos) intends to construct (redevelop), operate and eventually close/reclaim open pit gold mines at both these historical mine sites. The Gordon site is located approximately 55 kilometres (km) east of Lynn Lake, Manitoba (by vehicle), and the MacLellan site is located approximately 8 km northeast of Lynn Lake (by vehicle) (Map 1, Appendix A). Lynn Lake is located approximately 820 km northwest of Winnipeg.

This Hydrogeology Technical Modeling Report (TMR) for the Gordon site has been prepared to assess the potential effects of the construction, operation, and closure phases of the Project on groundwater resources and the consequent indirect effects on surface water resources at the Gordon site. The TMR considers the Gordon site components of the Project, baseline data collected for the Project since 2015, and comments received from agencies, Indigenous communities, and other stakeholders.

To evaluate the effects of the Project, a groundwater flow model has been developed for the Gordon site to provide estimates of:

- Changes in groundwater levels (drawdown), including changes to water table position and groundwater flow, due to dewatering of the historical East and Wendy pits and the open pit.
- The time to fill the open pit from groundwater inflow for use as an input to the water balance modelling conducted for the Project.
- Groundwater flow and discharge to wetlands, creeks and lakes under baseline, operation, and closure.
- Groundwater recharge and flow pathways from historical mine rock piles, overburden storage area, and MRSAs developed for the Project under operation and closure.
- Evaluation of mitigation options to control groundwater inflow to the open pit.

This TMR, and a companion TMR conducted for the MacLellan site (Stantec 2020b), form part of the supporting documentation for the Environmental Impact Statement (EIS)/Environmental Assessment (EA) completed for the Project.

2.0 BACKGROUND

This section provides an overview of the existing conditions that were used as background for the Gordon site hydrogeology model development. More detailed information is presented in the following reports:

- Hydrogeology Baseline Technical Data Report (Stantec 2017c).
- Hydrology Baseline Technical Data Report (Stantec 2017b).
- Hydrogeology Technical Data Report: Validation Report (Stantec 2020a).
- Hydrology Baseline Technical Data Report: Validation Report (Stantec 2020c).

2.1 HISTORICAL MINING OPERATIONS

Historical mining operations at the Gordon site consisted of the development of two primary ore pits, the Wendy Pit and East Pit (Map 2). The following is a summary of the historical mining operations described by KGS (2014).

The open pits were active between 1996 and 1999 and produced 214,800 oz of gold from 1.7 Mt of ore. The ore was transported to Lynn Lake for processing and smelting. Overburden was placed in two overburden storage areas, one north of the Wendy Pit and one north of the East Pit. Mine rock and low-grade ore not transported to Lynn Lake were placed in two MRSAs, one to the north of Wendy Pit and one to the south of Wendy and East pits. The north MRSA contained mine rock from the East Pit and was not considered potentially acid generating (PAG). Mine rock and low-grade ore from Wendy Pit was placed in the south MRSA. KGS (2014) characterized this material as containing about 10.5% PAG rock.

The historical open pits are located between Gordon and Farley Lakes (Map 2), which were historically connected via Gordon Creek. To allow the development of the open pits, a diversion channel was constructed so that discharge from Gordon Lake was directed through the diversion channel into Farley Lake. The water levels in Gordon and Farley lakes were reduced by 0.9 m as a result of the diversion channel (KGS 2014). Wendy Pit and East Pit were not connected to the diversion channel; however, KGS (2014) concluded that the East Pit and Farley Lake may be hydraulically connected via a historical buried stream channel.

Dewatering for the Wendy and East pits was conducted through a series of wells located between the open pits. Inflow to the open pits was collected and discharged with water from the dewatering wells to adjacent settling ponds, which were ultimately discharged to the southeast corner of Gordon Lake through a drainage channel.

Operation of the mine ceased in 1999 and a mine closure plan was submitted to the Manitoba Mines Branch and received conditional approval in August 1999. At closure, some of the PAG material was placed into Wendy Pit. The open pits were allowed to refill with water, which reduced the potential for oxidation and generation of acidic conditions from the PAG rock.

Reclamation work was completed in 2007 and consisted of ditching and drainage upgrades, berm repairs, and general fill placement. The mine rock storage areas were sloped to maximize runoff and were covered with 0.3 m of overburden from the overburden stockpiles and then hydroseeded in an effort to increase evapotranspiration and minimize infiltration.

Additional reclamation work was completed in 2012 and included installation of rock riffle control structures at the outlets of Gordon and Farley lakes to maintain water levels at pre-development elevations, repair berms around each of the open pits, removal of buildings, and general site cleanup (KGS 2014).

2.2 CLIMATE

The climate and meteorology of the Gordon site are detailed in the Climate and Meteorology Baseline Technical Data Report (Stantec 2017a). The Lynn Lake area has a climate typical of Northern Manitoba.

The nearest permanent weather monitoring stations are Environment and Climate Change Canada stations 5061645 and 5061649, located at the Lynn Lake Airport. The climate normals (1981 to 2010) average temperature, precipitation, and snow on ground statistics for the Lynn Lake Airport are summarized in Table 2-1.

Table 2-1 Climate Normals (1981 to 2010) Statistics at Lynn Lake Airport

Month	Monthly Average Temperature (°C)	Average Total Precipitation (mm)	Average Total Rainfall (mm)	Average Total Snowfall (mm)
January	-24	20	0.2	28
February	-20	16	0.1	24
March	-13	20	1.4	25
April	-3.1	24	4.5	24
May	5.6	37	27	10
June	13	62	61	1.3
July	16	85	85	0.1
August	15	69	69	0.1
September	7.7	61	57	3.5
October	-0.6	38	12	31
November	-13	27	0.8	36
December	-21	19	0.1	26
Annual	-3.2	478	318	208

The average monthly temperature is normally above freezing from May to September. The annual total precipitation for the region is 478 mm using the 1981 to 2000 climate normals, with 34% occurring as snow and 66% as rain. July typically receives the most monthly precipitation and February the least.

2.3 PHYSIOGRAPHY, TOPOGRAPHY, AND DRAINAGE

The Gordon site is surrounded by vegetated land, forest cover, scattered lakes, watercourses, and wetlands and is located within areas of discontinuous permafrost cover.

Regional topography around the Gordon site slopes from a high of 350 m above mean sea level (AMSL) in the west and northwest to a low of 320 m AMSL in the southeast (Map 4). The ground surface is characterized as hummocky with steeply sloping rocky ridges that may extend 30 m to 60 m above lakes and peat-filled depressions. Surface water features and peat deposits generally occupy the topographic lows.

2.4 REGIONAL GEOLOGIC CONTEXT

A summary of the regional geology is provided below. Additional information on the regional and local geology is provided in the Hydrogeology Baseline Technical Data Report (Stantec 2017c) and subsequent validation report (Stantec 2020a).

2.4.1 Overburden Geology

The regional surficial geology has been mapped by the Geological Survey of Canada as shown on Map 5 (Kaszycki et al. 2008). During the Late Wisconsinan period, the advance of the Keewatin ice centre (part of the Laurentide Ice Sheet) deposited glacial diamicton (diamicton) derived from the crystalline bedrock of the Canadian Shield. Meltwaters, resulting from the retreat of glacial ice, eroded and cut through the various glacial deposits and resulted in deposition of glaciofluvial sediments that are typically stratified and sorted to varying degrees. As the ice retreated, glacial Lake Agassiz was formed and resulted in the deposition of glaciolacustrine laminated silt and clay.

2.4.2 Bedrock Geology

The bedrock geology of the area has been described in detail by the Manitoba Geological Survey. The Gordon and MacLellan sites are located within part of the Lynn Lake greenstone belt, which is located in the Churchill Structural Province of the Canadian Shield. Map 6 presents the regional bedrock geology. The Lynn Lake greenstone belt is comprised of metamorphosed volcanic rocks of the Wasekwan Group, metamorphosed sedimentary rocks of the Sickle Group, and plutonic intrusions. The Lynn Lake greenstone belt trends west to east and extends 130 km from the La Ronge greenstone belt in Saskatchewan (MEM 1986). Structural processes altered the Lynn Lake greenstone belt into two belts (north belt and south belt), that are separated by felsic intrusions (Beaumont-Smith and Böhm 2003). The north and south belts differ by stratigraphic sequences, chemistry, and structure (MEM 1986).

The Gordon and MacLellan sites are located within the north belt, which is characterized as a north-dipping homocline comprised of rhyolite, overlain by andesite and sedimentary rocks, and an upper unit of basaltic rocks (MEM 1986). The north belt includes the unique stratigraphic sequence known as the Agassiz Metallotect (also termed “Rainbow Trend”) (Map 6), which consists of picritic flows, iron formation, and felsic volcanic rocks. The metallotect hosts the gold deposits of the Gordon and MacLellan sites. South of the sites lies the south belt, which consists of volcanic and sedimentary rocks and the east-west trending structural feature identified as the Johnson Shear Zone (Map 6). In some areas, these weathered shear zones may have been preferentially eroded because of the orientation of the shear zone relative to the direction of ice movement and the competence of the weathered bedrock in the shear zone relative to the surrounding bedrock units (Machibroda Engineering 1988).

The Gordon site has four zones of mineralization including the Wendy, East, Southeast, and the South zone (KGS 2014). The Wendy and East zones have been mined during historical mining activities. Two northwest trending parallel faults extend across the former Gordon pit areas from Gordon Lake in the west to south of Farley Lake in the east and are called the East and Wendy Faults (Map 6) (KGS 2014).

3.0 CONCEPTUAL MODEL

3.1 MODELLING APPROACH

The development of a conceptual model is the fundamental first step in the preparation of a numerical groundwater model. The conceptual model combines the available hydrologic and hydrogeologic data from a site and allows for the interpretation of the hydrostratigraphy and boundary conditions so they can be entered into a numerical groundwater flow model. The general approach used to develop the conceptual and numerical model was to add complexity as warranted by the available data to achieve the objectives of the numerical modelling (see Section **Error! Reference source not found.**).

The development of the conceptual model was facilitated by the use of the geologic modelling software, Leapfrog Hydro® Version 2.5.2. The software was used to create three-dimensional (3D) volumes for each of the defined hydrostratigraphic units in the conceptual model. Inputs for volume generation included wireframes for the ground surface topography, structural features, historical open pits, as well as contact points for the various lithologies defined from borehole and outcrop data. The Leapfrog Hydro® software can transfer the conceptual model directly to popular hydrogeology modelling software, including MODFLOW and FEFLOW.

3.2 CONCEPTUAL MODEL BOUNDARIES

The conceptual model boundaries were defined to coincide with or extend beyond the proposed limits for the groundwater flow model. Natural hydrologic and hydrogeologic boundaries such as watershed boundaries and surface water bodies were used to define the lateral extent of the conceptual model. The boundaries of the conceptual model correspond with the study area illustrated on Map 3. The model boundaries coincide with watershed boundaries as defined in the Hydrology Baseline Technical Data Report (Stantec 2017b). The boundaries of the conceptual model were constrained vertically by ground surface topography and extended 50 m below the base of the proposed open pit.

The conceptual model and groundwater flow model were developed based on the geologic and hydrogeologic data presented in the Hydrogeology Baseline Technical Data Report (Stantec 2017c).

3.3 HYDROSTRATIGRAPHY

The following hydrostratigraphic units are interpreted within the study area and are incorporated into the conceptual model. Details for each hydrostratigraphic unit are summarized in Sections 3.3.1 to 3.3.5:

- Historical Mine Rock
- Organics
- Glaciolacustrine nearshore
- Glaciolacustrine offshore
- Sand Diamicton
- Bedrock

Cross-sections depicting the geological interpretation of the hydrostratigraphic units across the study area are shown on Maps 7 and 8. The cross-section locations are presented on Map 4. Additional description of the hydrostratigraphic units is presented below, including references to monitoring well locations (Map 4), where appropriate.

3.3.1 Historical Mine Rock Storage Areas

Two historical MRSAs, identified on Map 2 as the historical north MRSA and the historical south MRSA. Both historical MRSAs are capped with native soils and contain surplus mine rock from historical mining operations at the Gordon site. Hydraulic testing of the historical mine rock was not completed due to their expected high hydraulic conductivity values and limited extent below the water table. Typical testing methods are difficult to perform under these conditions. Based on the grain size and material descriptions, hydraulic conductivity values for historical mine rock were estimated to vary between 1×10^{-3} and 1×10^{-2} metres per second (m/s) (Fetter 2000).

3.3.2 Organics

Organic deposits in the form of fibric peat and topsoil were observed at ground surface throughout the study area. Fibric peat is the least decomposed type of peat and generally consists of greater than 30% organic material or greater than 17% organic carbon. Topsoil was observed in upland portions of the landscape and was characterized as mineral soil with minor enrichment of organic material. Typical thicknesses were less than 1 m, but accumulations of up to 2.8 m were observed in low lying areas such as at monitoring well GBHF-06 (Map 4). Organic deposits were found underlying surficial fill in boreholes completed along the access road.

Hydraulic testing of the organic deposits was not completed due to their shallow nature and thickness. Hydraulic conductivity values from literature cover a wide range and are dependent on the texture of the sediments composing the organic deposit. Based on the geology and material descriptions, hydraulic conductivity values for organic deposits were assumed to vary between 1×10^{-8} and 1×10^{-5} m/s during model calibration (Fetter 2000).

3.3.3 Glaciolacustrine

Glaciolacustrine deposits were observed across the study area at either ground surface or underlying organic deposits. The glaciolacustrine deposits were discontinuous (Map 7 and Map 8). The glaciolacustrine deposits consisted of nearshore coarse-grained deposits and offshore fine-grained deposits. Nearshore and offshore deposits were generally observed to grade laterally between the two units; however, in some areas the units were interlayered (Map 7 and Map 8). These variations are interpreted to reflect changes to the level of former glacial Lake Agassiz.

Both nearshore and offshore deposits were observed in areas south of the open pit, including at monitoring wells GBHF-13 and MWF-04 (Map 4). When both deposits were present, the offshore deposits overlaid the nearshore deposits; when only one deposit was observed at a borehole, it was typically the nearshore deposits.

3.3.3.1 Glaciolacustrine Offshore

Offshore glaciolacustrine deposits are described as sandy clayey silt to clay and ranged in thickness from 0.8 m at monitoring well GBHF-13 to 6.2 m at monitoring well GBHF-05 when present. In the area of the proposed open pit, glaciolacustrine offshore deposits were predominant and ranged in thickness from 0.46 m at monitoring well GBHF-02 to 6.2 m at monitoring well GBHF-05.

Hydraulic conductivity estimates from slug tests conducted in the glaciolacustrine offshore deposits ranged from 6×10^{-7} to 1×10^{-6} m/s.

3.3.3.2 Glaciolacustrine Nearshore

The nearshore deposits are described as loose, fine to coarse grained sand to silty sand and gravel and ranged in thickness from 1.1 m at monitoring well MWF-06 to 9.6 m at monitoring well MWF-02 when present. Nearshore deposits of silty sand were observed in boreholes located along the eastern edge of the proposed open pit associated with monitoring wells GBHF-03, GBHF-04, GBHF-06, GPW-01, and GPW-02 ranging in thickness from 0.6 m to 4.5 m.

Hydraulic conductivity estimates from slug tests conducted in the glaciolacustrine nearshore deposits ranges from 3×10^{-7} to 1×10^{-4} m/s.

3.3.4 Sand Diamicton

Sand diamicton was frequently observed throughout the Gordon site. Despite the frequency of encountering the sand diamicton, the unit was interpreted as discontinuous, having been eroded by meltwaters associated with the retreat of glacial ice (Map 7 and Map 8). When present, sand diamicton overlaid bedrock and was overlain by glaciolacustrine or organic deposits. The sand diamicton was generally observed south and east of the proposed open pit but thinned in the area of the topographic and bedrock high located south of the Wendy and East pits. Sand diamicton was comprised of very dense sand to silty sand with trace to some gravel and at times contained trace cobbles and boulders. The thickness of the sand diamicton generally ranged from less than 1 m to about 4 m.

Hydraulic conductivity estimates from slug tests conducted in the glaciolacustrine offshore deposits ranged from 2×10^{-7} to 3×10^{-5} m/s.

3.3.5 Bedrock

Bedrock was defined as a continuous unit throughout the study area and the top of bedrock surface described in Stantec (2017c) was interpreted from the boreholes and test pits installed at the Gordon site, including boreholes drilled for exploration and condemnation purposes. The bedrock topography was interpreted to follow a similar trend to ground surface topography, with a topographic high associated with the area south of the Wendy and East pits (monitoring well GBHF-13; Map 4), which steeply slopes to the south towards Susan Lake (monitoring well MWF-04; Map 4) and gradually slopes to the north toward the Wendy and East pits. Bedrock was observed near surface (less than 1 m below ground surface [BGS]) in areas associated with topographic highs and between 1 and 10 m BGS in areas associated with topographic lows. Local bedrock lows were observed at monitoring wells GBHF-12 and GBHF-09 (Map 4). These bedrock lows were interpreted to be local in extent. Across the Gordon site, the top of bedrock was encountered at elevations ranging from 298 m AMSL at monitoring well GBHF-27 to 342 m AMSL at monitoring well GBHF-13, with a relief of 44 m.

The hydraulic conductivity of the bedrock decreases with depth, with the upper portions being the most transmissive due to increased weathering and/or fracturing. The bedrock was subdivided into four hydrostratigraphic units based on transmissivity data collected from hydraulic testing conducted in the study area (Stantec 2017c). These units include the shallow bedrock, upper bedrock, intermediate bedrock, and deep bedrock units. A comparison of the measured hydraulic conductivity in the bedrock for each of the hydrostratigraphic units is presented on Figure 3-1. The hydraulic conductivity was observed to be variable across each hydrostratigraphic unit, as described below.

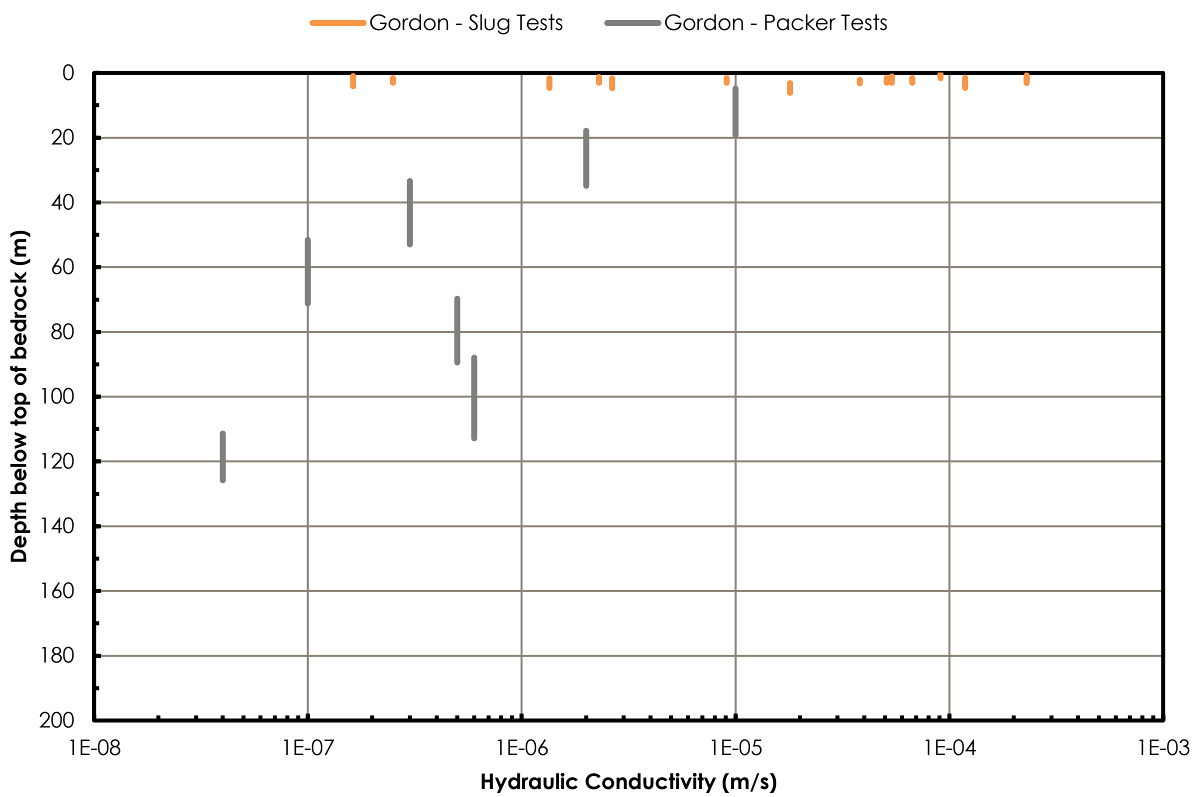

Figure 3-1 Hydraulic Conductivity Distribution in Bedrock with Depth

3.3.5.1 Shallow Bedrock

The shallow bedrock unit consists of a zone of weathered and fractured bedrock that exists below the overburden deposits or at ground surface where bedrock is exposed. The shallow bedrock is estimated to be approximately 50 m thick, with hydraulic conductivity estimates ranging from 2×10^{-7} to 2×10^{-4} m/s (Figure 3-1).

Two mapped faults (East Fault and Wendy Fault) occur in the areas of monitoring wells GPW-01, GPW-02, and GPW-04 (Map 4). The aquifer parameters of shallow bedrock estimated from pumping tests at GPW-01, GPW-02, and GPW-04 are assumed to be reflective of a zone of higher hydraulic conductivity associated with historical blasting and the presence of the fault zones. The faulted shallow bedrock zone relative to shallow bedrock are illustrated on Map 9.

Hydraulic conductivity estimates in the faulted shallow bedrock zone were estimated to be at the higher end of the estimates of hydraulic conductivity of the shallow bedrock. Storativity estimates from pumping tests in the shallow bedrock ranged from 4.5×10^{-5} to 2.2×10^{-3}.

3.3.5.2 Upper Bedrock

The upper bedrock unit underlies the shallow bedrock unit and is estimated to be 50 m thick. The hydraulic conductivity for the upper bedrock is estimated to range from 1×10^{-7} to 6×10^{-7} m/s (Figure 3-1).

3.3.5.3 Intermediate Bedrock

The intermediate bedrock unit underlies the upper bedrock and is estimated to be 50 m thick. The hydraulic conductivity for the intermediate bedrock is estimated to range from 4×10^{-8} to 6×10^{-7} m/s (Figure 3-1).

3.3.5.4 Deep Bedrock

The deep bedrock unit is the deepest bedrock unit and is considered to be relatively impermeable, although discrete fractures may occur that increase the hydraulic conductivity locally. The hydraulic conductivity of this unit is estimated to range from less than 4×10^{-8} m/s (based on the hydraulic conductivity of bedrock with limited to no interconnected fractures) to 6×10^{-7} m/s (where fractures are present) (Figure 3-1).

4.0 MODEL CONSTRUCTION AND CALIBRATION

This section describes the construction of the hydrogeology model using the hydrostratigraphic units of the conceptual model described in Section 3.0. The calibration of the model using available information on water levels and streamflow measurements collected as part of the baseline monitoring programs is also described.

The FEFLOW (version 7) groundwater modelling platform was chosen for this evaluation. It is a common platform for simulating and predicting groundwater flow in mining environments. In addition, it was selected as it is able to simulate heat transport and freeze-thaw processes (through a plug-in module) that affect the near-surface hydraulic conductivity. These processes were considered based on the discontinuous permafrost observed at the site.

An equivalent porous media (EPM) approach was selected to simulate the flow within the overburden and underlying bedrock. The EPM approach assumes that groundwater flow through fractured bedrock can be approximated by a porous medium with equivalent hydrogeologic properties of the bulk of the rock. The shallow weathered bedrock in the study area has the highest hydraulic conductivity reflecting the increased fracturing that is typical of shallow weathered bedrock in the Canadian Shield (see Section 3.3.5). The water level data within the shallow bedrock monitoring wells indicates a similar hydraulic response to the overburden system indicating a high degree of connectivity. Cook (2003) demonstrates regional connectivity occurs within the shallow bedrock zone and decreases with depth due to a decrease in fracture frequency and permeability. Groundwater flow in the bedrock is therefore expected to occur dominantly through the upper portions of this shallow bedrock unit.

As shown in Section 3.3.5, the permeability of the bedrock decreases with increasing depth, due to more discrete fracturing of the bedrock. At the regional scale, the EPM approach remains appropriate for predicting the effective groundwater discharge rates from the deeper bedrock into the open pit but reduces the reliability of predicted travel times through discrete fractures (Wels et al. 2012). Travel times through the discrete fractures using the EPM approach could be under-predicted (due to lower effective fracture porosities in the bedrock), or over-predicted, if there is poor connectivity of fractures at depth. This is appropriate based on the regional scale of the modelling and considering that flow was predicted to occur primarily through the shallow weathered bedrock, which is highly fractured, and therefore behaves like a porous medium.

4.1 MODEL DOMAIN

The extent of the model domain was chosen to correspond to both natural hydrogeologic boundaries and was extended to beyond the area where potential effects from the model predictions may impact on model boundaries. The model domain is presented on Map 10.

The model mesh is simulated to grade from coarser around the limits of the domain, to finer in the vicinity of the surface water features and the area of the proposed open pit. The mesh is composed of a total of 160,764 elements in each model layer with a total of 28 model layers.

The hydrostratigraphic units described in Section 3.0 were transferred to the FEFLOW model via the groundwater flow model output utility in Leapfrog Hydro®, with each hydrostratigraphic unit corresponding to a model layer presented in Table 4-1. Where hydrostratigraphic units were observed to be discontinuous across the study area and "pinch out", the model layer was assigned a minimum thickness of 0.1 m and the hydraulic properties of the underlying hydrostratigraphic unit were assigned. The properties of the model layers are discussed further in Section 4.4.

Table 4-1 Relationship of Hydrostratigraphic Units and Model Layers

Hydrostratigraphic Unit	Model Layers	Thickness (m)
Overburden	1-5	Varies with hydrostratigraphic units
Shallow Bedrock & Faulted Shallow Bedrock	6-12	50
Upper Bedrock	13-19	50
Intermediate Bedrock	20-23	50
Deep Bedrock	24-28	Varies to bottom of model domain (elevation 115 m AMSL)

4.2 DISTRIBUTION OF HYDROGEOLOGIC PARAMETERS

The hydraulic conductivity, porosity, and recharge rate were assigned in the model based on the hydrostratigraphic units as defined in the conceptual model (Section 3.0). The geometric mean hydraulic conductivity values for each unit determined from the field-testing programs or characterized from grain size were used in the initial model set-up. The hydrostratigraphic units were assumed to be uniform and isotropic.

4.3 BOUNDARY CONDITIONS

4.3.1 Model Boundary

The model limits were assigned based on local watershed boundaries but were extended into neighbouring watersheds based on anticipated effects from the presence of the open pit. In all cases the model was extended to natural hydrologic/hydrogeologic boundaries, including watershed boundaries (assumed to be coincident with groundwater flow divides) or surface water features (also assumed to be coincident with groundwater flow divides). The model domain limits are presented on Map 10.

4.3.2 Recharge

The type of soil and vegetation present at surface is an important factor in determining whether precipitation will become runoff or groundwater recharge. Recharge rates were assigned based on the hydrostratigraphic units exposed at the top of the model domain and consideration of the surficial geology mapping for the area. The groundwater recharge rate was adjusted for each of these major groups during the model calibration process.

4.3.3 Lakes and Watercourses

As shown on Map 10, several lakes and watercourses are located within the model domain. Lakes and watercourses were assigned as boundary conditions in the model using a head-dependent flux boundary.

This type of boundary condition determines the flow rate between the boundary condition and the aquifer based on the head assigned to the boundary condition. The vertical extent of the lakes was determined using available bathymetric data collected at the lakes (Stantec 2017c).

The interaction between the surface water in the lakes and watercourses and the groundwater in the underlying aquifers is defined by a “conductance” term. This term represents the presence of a layer of sediment on the lakebed or streambed that can affect the rate of water transferred between the lake or watercourse and the underlying model layer. A review of sediment analyses from lakes and watercourses showed that the sediments are generally fine-grained (Stantec 2017b), and the conductance term was assigned to the model based on an assumed hydraulic conductivity of 1×10^{-7} m/s.

4.4 CALIBRATION

4.4.1 Calibration Methodology

Model calibration was conducted using an iterative approach under steady-state conditions, followed by additional iterations to evaluate transient conditions. This involved a process where a flow simulation was carried out, the resulting groundwater levels and baseflow rates to watercourses were compared to measured values, and the model input parameters were re-adjusted to achieve better agreement with observed (field measured) conditions and the overall interpreted groundwater flow directions. The process of model calibration involves the adjustment of model parameter values to match field-measured values within a pre-established range of error. A hybrid calibration approach was used that combined automated parameter estimation, facilitated using the parameter estimation code PEST (Doherty 2009), together with professional judgement and interpretation of the calibration results.

The calibration was completed using the following steps:

1. Prepare model files and input parameters
2. Run PEST to estimate parameter values that provide the best average fit to the observations
3. Review the model results
4. Adjust insensitive parameters from the PEST calibration (if any can be identified)
5. Repeat steps 2 through 4 until the model is determined to be adequately calibrated within acceptable ranges of error

Several parameters were adjusted during the calibration of the model, including:

- Hydraulic conductivity
- Specific yield
- Specific storage

These parameters were adjusted automatically using PEST over the ranges determined from field observations or literature values. A total of 34 parameters were adjusted during the calibration process. Key areas where manual adjustments in the automated calibration process were required included:

- Annual recharge rate (steady-state)
- Monthly recharge rates (transient)
- Hydraulic conductivity of deep bedrock

4.4.2 Calibration to Water Levels

Model calibration was assessed by comparing model-simulated water levels to observations collected from two water level datasets:

- Average annual water levels calculated from transient water levels
- Continuous water level data collected from onsite monitoring wells using pressure transducers and data recorders

The average annual water level targets at each location were calculated as the mean water level observed during the period of record available for each location and were used for the first calibration to steady-state conditions. Continuous water level observations from wells instrumented with pressure transducers were then used to attempt to fit transient water level targets based on transient recharge rates. The calculated average annual water level targets are presented in Table 4-2. The location of the water level targets is shown on Map 11.

Table 4-2 Water Level Calibration Residuals and Statistics

Location	Average Annual Water Level Target (m AMSL)	Simulated Average Annual Water Level (m AMSL)	Residual (m)	Target Type
MWF-01A	321.75	322.98	-1.23	Steady-state
MWF-02A	317.37	318.83	-1.46	Steady-state
MWF-02B	317.28	318.81	-1.53	Steady-state
MWF-03A	325.42	325.56	-0.14	Steady-state
MWF-03B	325.44	325.63	-0.19	Steady-state
MWF-04A	314.06	314.99	-0.93	Steady-state
MWF-04B	313.73	314.85	-1.12	Steady-state
GBHF-01A	314.85	315.36	-0.51	Steady-state
GBHF-01B	314.85	315.38	-0.53	Steady-state
GBHF-02A	315.48	315.19	0.29	Steady-state
GBHF-04A	314.31	315.40	-1.09	Steady-state
GBHF-04B	314.59	315.43	-0.84	Steady-state
GBHF-05B	314.54	315.78	-1.24	Steady-state
GBHF-07A	317.97	318.60	-0.63	Steady-state
GBHF-07B	318.08	318.59	-0.51	Steady-state
GBHF-09A	317.25	317.30	-0.05	Steady-state
GBHF-09B	317.05	317.25	-0.20	Steady-state
GBHF-10A	326.12	325.49	0.63	Steady-state
GBHF-12B	323.85	324.44	-0.59	Steady-state

Table 4-2 Water Level Calibration Residuals and Statistics

Location	Average Annual Water Level Target (m AMSL)	Simulated Average Annual Water Level (m AMSL)	Residual (m)	Target Type
Residual Statistics				
Sum of Squared Error (m²)			13.7	
Mean Error (m)			0.62	
Absolute Mean Error (m)			0.72	
Root Mean Squared Error (m)			0.85	
Normalized Mean Squared Error (%)			6.8	

A plot of the simulated (modelled) versus observed (measured) average annual groundwater levels is shown in Figure 4-1. A line of perfect fit (e.g., a line having a slope of 1.0) is shown for comparison. Simulated groundwater levels that match the observed groundwater levels exactly will fall on this line. As shown on Figure 4-1 and in Table 4-2, there is generally good agreement with the water level targets; however, there is a slight overprediction bias to the residuals.

The statistical measures of the calibration to the water level data are reported in Table 4-2. These measures include the standard error of the estimate and the root mean squared (RMS) error. In evaluating the fit between the observed and the simulated water levels, the RMS error is usually regarded as the best measure (Anderson and Woessner 1991). The RMS error is essentially a standard deviation calculated as the average of the squared differences between the measured and the simulated water levels. If the ratio of the RMS error to the total water level differential over the model area is small (e.g., less than 10%; Spitz and Moreno 1996), then the errors are only a small part of the overall hydraulic response of the model. In this simulation, the ratio of the RMS error to the total water level differential (6.8%) is less than the recommended 10% threshold. No systematic bias was observed in the residuals considering hydrostratigraphic units or proximity to boundary conditions.

The fit of the model predicted transient water level trends to the observed water level hydrographs are provided in Figure 4-2. As shown, the model is able to produce reasonable matches to the shape of the observed water level trends by varying the recharge on a monthly basis and adjusting the storage parameters (specific yield and specific storage) over the expected ranges during calibration. However, the model was relatively insensitive to the calibration parameters adjusted at monitoring wells with more than 1 m of variability in the transient water level hydrographs.

4.4.3 Calibration to Baseflow

The steady-state model calibration also included baseflow targets for a surface water monitoring location at the outlet of Farley Lake (QF05, Map 11). Streamflow data were developed from continuous water level data and flow measurements completed between 2015 and 2016 (Stantec 2017b). The average annual streamflow rate at the outlet of Farley Lake is estimated to be approximately 0.06 cubic metres per second (m^3/s).

Baseflow to surface water features is provided primarily by groundwater discharge. However, a portion of the baseflow can also be attributed to the delayed drainage of precipitation storage in lakes and wetlands. This delayed release surface water storage can be difficult to distinguish from groundwater contributions to baseflow. Therefore, the baseflow targets determined from surface water hydrographs include both of these components.

The model simulated average annual (i.e., steady-state) groundwater discharge contributing to the total Farley Lake discharge is 0.012 m^3/s, or approximately 20% of the average annual streamflow. This was considered to be a reasonable estimate of baseflow for this watershed, and therefore, the calibration to baseflow is considered acceptable for this model.

4.4.4 Calibrated Model Parameters

The values of the hydrogeologic parameters that were determined from the calibration process are presented in Table 4-3. The hydraulic conductivity and storage coefficient values for the various hydrostratigraphic units generated by the model are within the ranges expected for the materials based on measured and literature values, as these were set as part of the calibration process.

Table 4-3 Calibrated Model Parameters

Parameter	Hydraulic Conductivity (m/s)	Specific Yield (-)	Specific Storage (1/m)	Average Annual Recharge (mm/yr)
Historical mine rock • Calibrated Value • Expected Range	• 1×10^{-3} • 1×10^{-3} to 1×10^{-2}	• 0.16 • 0.01 to 0.3	• 1.1×10^{-4} • 1×10^{-6} to 1×10^{-3}	• 16 • 4 to 146
Organics • Calibrated Value • Expected Range	• 1×10^{-6} • 1×10^{-8} to 1×10^{-5}	• 0.19 • 0.01 to 0.3	• 1.0×10^{-4} • 1×10^{-6} to 1×10^{-3}	• 16 • 4 to 146
Glaciolacustrine offshore • Calibrated Value • Expected Range	• 6.5×10^{-7} • 6×10^{-7} to 1×10^{-6}	• 0.30 • 0.01 to 0.3	• 1.0×10^{-4} • 1×10^{-6} to 1×10^{-3}	• 33 • 4 to 146
Glaciolacustrine Nearshore • Calibrated Value • Expected Range	• 1.2×10^{-5} • 3×10^{-7} to 1×10^{-4}	• 0.016 • 0.01 to 0.3	• 2.0×10^{-4} • 1×10^{-6} to 1×10^{-3}	• 33 • 4 to 146

Parameter	Hydraulic Conductivity (m/s)	Specific Yield (-)	Specific Storage (1/m)	Average Annual Recharge (mm/yr)
Sand Diamicton • Calibrated Value • Expected Range	• 2.3×10^{-7} 2×10^{-7} to 3×10^{-5}	• 0.20 0.01 to 0.3	• 1.0×10^{-4} 1×10^{-6} to 1×10^{-3}	• 16 4 to 146
Shallow Bedrock • Calibrated Value • Expected Range	• 1.2×10^{-6} • 2×10^{-7} to 2×10^{-4}	• 0.06 • 0.01 to 0.3	• 1.0×10^{-4} • 4×10^{-5} to 2×10^{-3}	• 5 • 4 to 146
Faulted Shallow Bedrock • Calibrated Value • Expected Range	• 1.2×10^{-5} • 1×10^{-5} to 2×10^{-4}	• 0.06 • 0.01 to 0.3	• 1.0×10^{-4} • 4×10^{-5} to 2×10^{-3}	• 5 • 4 to 146
Upper Bedrock • Calibrated Value • Expected Range	• 7×10^{-7} • 1×10^{-7} to 6×10^{-7}	n/a	• 1.0×10^{-4} • 4×10^{-5} to 2×10^{-3}	n/a
Intermediate Bedrock • Calibrated Value • Expected Range	• 1×10^{-7} • 4×10^{-8} to 6×10^{-7}	n/a	• 1.0×10^{-4} • 4×10^{-5} to 2×10^{-3}	n/a
Deep bedrock • Calibrated Value • Expected Range	• 5×10^{-8} • 4×10^{-8} to 6×10^{-7}	n/a	• 1.0×10^{-4} • 4×10^{-5} to 2×10^{-3}	n/a

The transient recharge rates determined at the end of the calibration are presented on Table 4-4.

Table 4-4 Calibrated monthly recharge rates (mm/month)

Month	Recharge Zone 1	Recharge Zone 2	Recharge Zone 3
January	0.1	0.1	0.02
February	0.1	0.1	0.02
March	0.1	0.2	0.03
April	1.8	3.7	0.56
May	1.6	3.2	0.49
June	2.9	6.0	0.91
July	2.6	5.4	0.81
August	1.3	2.7	0.41
September	3.0	6.3	0.95
October	1.9	4.0	0.61
November	0.4	0.9	0.13
December	0.2	0.5	0.07

Notes:

- Recharge Zone 1 includes Historical Mine Rock, Organics, and Sand Diamicton hydrostratigraphic units
- Recharge Zone 2 includes Glaciolacustrine offshore and Glaciolacustrine nearshore hydrostratigraphic units
- Recharge Zone 3 includes Shallow Bedrock and Faulted Shallow Bedrock hydrostratigraphic units

5.0 MODEL APPLICATIONS

The calibrated groundwater flow model was used to quantify baseline groundwater levels and flow and groundwater discharge to the receiving environment under baseline conditions. The baseline model results were then used to compare to model predictions during construction, operation, and closure phases of the Project. Section 5.1 presents the results from the baseline simulations using the calibrated model. Model modifications were then completed to allow simulation of the following phases:

- Construction (Mine Years -2 to 0) – dewatering of the existing East and Wendy open pits and initial dewatering of the starter pit.
- Operation (Mine Years 0 to 5) – dewatering of open pit and groundwater discharge and seepage collection associated with the historical and new MRSAs.
- Active reclamation/closure (after Mine Year 6) – filling of the open pit and groundwater discharge associated with the MRSAs.

Model results for the construction, operation, and closure phase of the Project are discussed in Sections 5.2 to 5.4, respectively.

5.1 BASELINE CONDITIONS

The calibrated groundwater flow model discussed in Section 4.0 was used to estimate the water table elevation (i.e., the top of the saturated water column) and groundwater flow under baseline conditions.

Map 12 shows the average annual water table elevation contours under baseline conditions from the calibrated groundwater flow model. The model provides a good representation of groundwater flow conditions in the area of the open pit and mimics the ground surface contours (Map 4), with groundwater flowing regionally to the east in the central and southern portions of the model domain and to the northeast in the northern portion of the domain. Groundwater flow converges locally on Gordon and Farley lakes in the central portion of the model domain.

An estimate of groundwater discharge to the primary lakes and watercourses located within the model domain was determined from the model and is presented in Table 5-1. The locations of surface water features are presented in Map 10. The groundwater discharge rates were used to quantify changes to groundwater discharge during the construction, operation, and closure phases, as presented in Sections 5.2 to 5.4.

In Table 5-1, a positive number for the net groundwater to receiver indicates groundwater discharge to the surface water feature and a negative value indicates that the surface water feature is recharging the groundwater flow system. Baseflow values presented in the table represent the groundwater contributions to the features, and do not include contributions from surface water storage.

Table 5-1 Estimated Groundwater Discharge (m^3/s) to Watercourses and Lakes under Baseline Conditions

Watercourse	Groundwater to Surface Water	Surface Water to Groundwater	Net Groundwater to Surface Water[1]
Lakes			
Susan Lake	0.00041	0.00005	0.00036
Pump Lake	<0.00001	0.00028	-0.00028
Marnie Lake	0.00031	0.00058	-0.00027
Gordon Lake	0.00074	0.00016	0.00058
Farley Lake	0.00450	0.00209	0.00241
Marie Lake	0.00313	0.00232	0.00081
Unnamed South Lake (FAR4-A2)	<0.00001	0.00004	-0.00004
Watercourses			
Watercourse connecting Susan and Marrow Lakes (SUS3)	0.00044	0.00009	0.00035
Tributary of Simpson Lake (FAR3-SIM2)	0.00057	0.00034	0.00023
Tributary of Swede Lake (FAR3-A1)	0.00089	0.00006	0.00083
Watercourse connecting Unnamed South Lake and Farley Lake (FAR5-MAN1)	<0.00001	0.00024	-0.00023
Tributary of Farley Lake (FAR5-A1)	0.00003	0.00014	-0.00012
Southern Tributary of Gordon Lake (FAR7-A1)	0.00006	0.00045	-0.00039
Diversion Channel (FAR6)	0.00001	0.00030	-0.00029
Watercourse connecting Marie and Farley Lakes (FAR5-MAR1)	0.00004	0.00012	-0.00008
Watercourse connecting Marie and Farley Lakes (FAR5-MAR3)	0.00013	0.00009	0.00004
Northern Tributary of Gordon Lake (FAR7-B1)	0.00010	0.00063	0.00058

NOTES:

1. - Positive value represents flow from groundwater to surface water
   - Negative value represents flow from surface water to groundwater

5.1.1 Historical Mine Rock Storage Areas

The historical MRSAs (north and south) are located at the Gordon site as shown on Map 2. Recharge through the MRSAs has the potential to affect groundwater quality and as a result the model was used to determine the discharge location and flux of water recharging the groundwater flow system from beneath the MRSAs. The historical MRSAs were incorporated into the model to understand the fate of recharge associated with these features. To provide a conservative estimate of the groundwater discharge originating from the historical MRSA, groundwater flow simulations were conducted without the contact water collection system.

The calibrated groundwater flow model was used to better understand the fate of groundwater that originates from the historical MRSAs and to estimate discharge rates to the receiving environment. A forward particle tracking approach was used, where a particle was released from each model node within the historical MRSAs. The travel paths of the particles were simulated through the model domain until they arrived at a receptor, such as a lake or watercourse. For this analysis, it was assumed that no subsurface seepage collection systems were in operation to provide a prediction of the maximum possible groundwater loading to the environment. This approach provides a conservative assessment of potential effects to the receiving environment.

The groundwater flux associated with each particle track was then determined and used to estimate the total discharge rate (Q) for the historical MRSAs to the environment. This is illustrated on the conceptual cross-section shown in Figure 5-1 below. A particle trace is shown for a particle that originates in a historical MRSA and terminates at a lake. The groundwater discharge to the lake that is contributed by the cell in the historical MRSA is conservatively assumed to be equal to the total average annual recharge rate into that element (e.g., Q_{in} = Q_{out}) during the various phases of mine development. It was assumed that the groundwater recharge that enters a historical MRSA will be carried through to the receptors. As a result, the groundwater flow model may over-estimate groundwater discharge rates, as local seepage to intermittent surface water features or ditches that may be present in the area of a historical MRSA are not accounted for in the model.

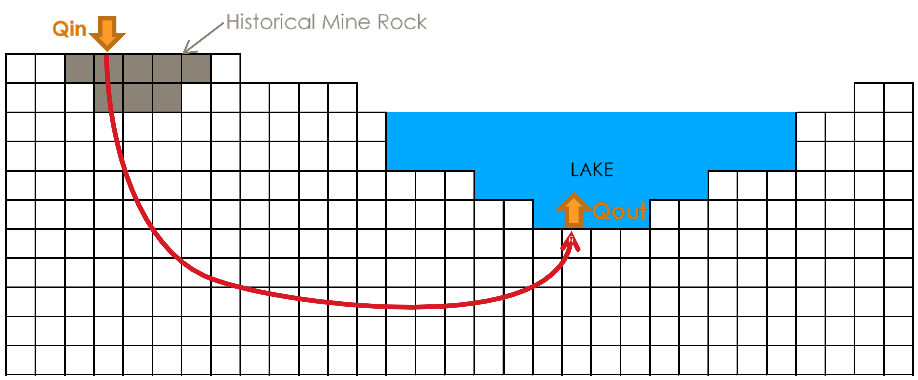

Figure 5-1 Conceptual Model Cross-Section Illustrating Particle Traces

The historical north MRSA and south MRSA received an average recharge rate of 16 mm/yr under baseline conditions. The particle tracks from the historical MRSAs under baseline conditions are presented on Map 13, and the estimated discharge rates and travel time statistics to the receiving environment are presented on Table 5-2. As shown on Map 13 and Table 5-2, the particles originating from the historical north MRSA discharge to Gordon Lake at a rate of 6.4×10^{-6} m/s or to Wendy Pit at a rate of 6.6×10^{-6} m/s. However, these flow paths are very long as they flow into the bedrock unit, and the estimated travel time from the water table to the receptors are estimated to exceed 80 years. The particles originating from the historical south MRSA discharge to Farley Lake at 1.3×10^{-4} m^3/s, East Pit at 8.6×10^{-6} m^3/s, and Wendy Pit at 2.2×10^{-6} m^3/s. The minimum travel times to Farley Lake and Wendy Pit are relatively short based on the proximity of the MRSA to these features; however, the average travel time is much longer as the majority of seepage flows through the bedrock.

Table 5-2 Predicted Groundwater Discharge Rates (m^3/s) from Historical Mine Rock Storage Area to Receiving Environment at Baseline

Mine Rock Storage Area	Receptor	Discharge (m^3/s)	Travel Time (years)		
			Minimum	Mean	Maximum
Historical North MRSA	Gordon Lake	6.4×10^{-6}	83	156	286
	Wendy Pit	6.6×10^{-6}	176	303	506
Historical South MRSA	Farley Lake	1.3×10^{-4}	0.1	246	762
	East Pit	8.6×10^{-6}	62	259	823
	Wendy Pit	2.2×10^{-6}	1.5	424	969

5.2 CONSTRUCTION

The primary activities that are anticipated to potentially influence groundwater levels and flow during construction include the initial dewatering of the existing East and Wendy open pits, mitigation of pit inflows through the use of interceptor wells, and the alteration of the historical south MRSA. While these activities will continue into the initial operating years, they have been simulated separately in the construction phase to document the potential changes to groundwater levels and flow in the early phases of Project development.

5.2.1 Model Setup

Starting with the calibrated groundwater flow model, the following modifications were completed to represent the dewatering of Wendy and East pits, the use of groundwater interception wells to mitigate pit inflow, and the fate of groundwater originating from the alteration of the historical south MRSA. The modifications are discussed below for each Project component.

5.2.1.1 Dewatering East and Wendy Pits

The construction and operation of the open pit has the potential to change the baseline groundwater flow conditions, particularly through the lowering of the water table in the vicinity of the open pit. The lowering of the water table may also affect groundwater discharge to surface water features near the open pit and the discharge associated with the historical MRSAs.

To evaluate the effects of groundwater inflows to the East and Wendy pits during the construction phase, the calibrated groundwater flow model was modified to represent the extent and depth of the existing pits as seepage faces instead of head-dependent flux boundaries during the construction period. The conductance of the seepage face nodes was specified based on the hydraulic conductivity in the elements surrounding the nodes.

The hydraulic conductivity of the seepage face nodes was adjusted on a monthly basis to reflect the reduced hydraulic conductivity based on freezing and thawing of the seepage face. The hydraulic conductivity was determined using the heat and transport functionality of FEFLOW with the Freeze Thaw Model (FTM) plugin. Simulations of the freezing and thawing were used to determine the changes in hydraulic conductivity predicted based on the average monthly air temperatures. Due to the additional computational burden of running the model in heat and transport mode, the simulation of effects of freezing on dewatering were conducted with only the flow components in FEFLOW, using the variable hydraulic conductivity at the pit face due to freezing as inputs that was determined using the FTM plugin.

5.2.1.2 Groundwater Interceptor Wells

A high permeability zone in the shallow bedrock associated with the East and Wendy faults was identified during the model calibration (Map 9). Initial model runs identified that dewatering of the existing pits has a strong hydraulic connection between the pits and Gordon and Farley lakes due to this high permeability zone in shallow bedrock. To control the inflows to the open pit, 13 interceptor wells were simulated in the groundwater flow model between the pits and the lakes within the higher permeability zone, as shown on Map 9. Seven interceptor wells are located between Farley Lake and the open pit and six interceptor wells are located between Gordon Lake and the open pit. Each interceptor well was assumed to extend from the top of rock to the base of the shallow bedrock layer (i.e., the top 50 m of bedrock). The number of pumping wells, and the pumping rate from each well was optimized to intercept groundwater originating from the lakes before it entered the open pit. The pumped water from the interceptor wells was assumed to be discharged to the nearest lake (Gordon or Farley). The optimal pumping rates for each well was estimated to be 0.014 m^3/s for a total combined pumping rate of 0.182 m^3/s year-round, which is a conservative assumption as required pumping from the interceptor wells in the winter may decrease due to the open pit wall freezing.

The operation of the interceptor wells has the potential to change the baseline groundwater flow conditions, particularly through the lowering of the water table in the vicinity of the wells. The lowering of the water table may also affect groundwater discharge to surface water features located near the open pit.

To evaluate the effects of the operation of the interceptor wells during the construction phase, the calibrated groundwater flow model was modified to represent the interceptor wells pumping at 0.014 m^3/s each for the top 50 m of bedrock using a specified flux boundary condition.

5.2.1.3 Historical Mine Rock Storage Areas

The calibrated groundwater flow model was used to better understand the fate of groundwater that originates from the historical MRSAs and to estimate discharge rates to the receiving environment. A forward particle tracking approach was used, where a particle was released from each model node within the historical MRSAs, as presented in Section 5.1.1. However, the footprint of the historical MRSAs are adjusted based on the removal of mine rock from these areas during construction, to accommodate the expansion of the open pit during operation.

5.2.2 Results

5.2.2.1 Open Pit Dewatering

The predicted total groundwater inflow rates to the existing East and Wendy pits are presented on Figure 5-2 for mine years -2 to -1. The groundwater inflow rates are predicted to be initially high (0.145 m^3/s for the first month), with decreasing flows during the winter months, followed by peak flows associated with the spring freshet. The average annual groundwater inflow rate to the pits is predicted to be 0.023 m^3/s at the end of the construction period.

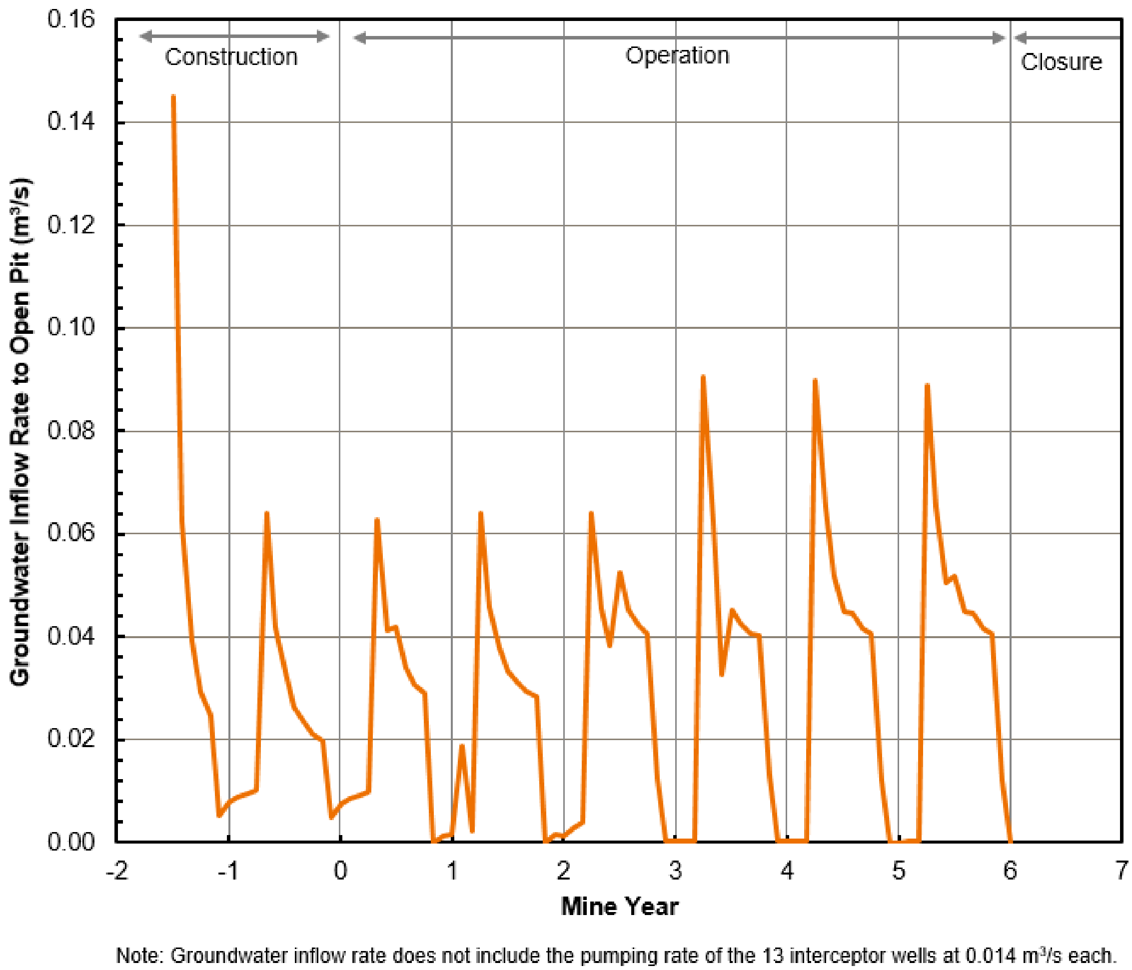

Figure 5-2 Calculated Groundwater Inflows to Historical East and Wendy Pits (Mine Years -2 to -1) and Open Pit (Mine Years -1 to 6) Over Life of Mine - Construction and Operation

The predicted groundwater elevation and drawdown contours at the end of construction period are presented on Maps 14 and 15, respectively. In the area of the East and Wendy pits, groundwater levels are lowered by approximately 1.0 m or less within 800 m of the pits, including the drawdown effect from the interceptor wells. The drawdown extends predominantly north and south of the East and Wendy pits due to the constraints of Gordon and Farley lakes.

Table 5-3 presents the comparison of baseline groundwater discharge rates with effects of the dewatering at the end of the construction period. As shown in Table 5-3, the groundwater flow system responds to the dewatering of the existing pits at the end of the construction period. Gordon, Farley, and Marie Lakes are predicted to shift from gaining groundwater to losing groundwater. The largest change in groundwater discharge is predicted at Farley Lake, which is predicted to contribute 0.010 m^3/s more flow than during baseline conditions. The water pumped from the interceptor wells will be returned to Gordon and Farley lakes during construction to offset a reduction in groundwater discharge. Groundwater discharge to Marie Lake is reduced by 227 m^3/d at the end of construction compared to baseline conditions. The diversion channel is a groundwater recharge feature under baseline conditions with recharge from the channel to groundwater increasing by 0.005 m^3/s at the end of construction compared to baseline conditions.

The changes to the groundwater discharge rates for remaining lakes and watercourses are relatively small (generally less than 0.001 m^3/s) compared to the overall anticipated flow rates in the surface water features.

Table 5-3 Estimated Groundwater Discharge to Watercourses and Lakes at End of Construction (m^3/s)

Watercourse	Baseline[1]	End of Construction[1]	Change from Baseline[1]
Lakes

NOTES:
1. Positive value represents flow from groundwater to surface water
   Negative value represents flow from surface water to groundwater

5.2.2.2 Mine Rock Storage Areas

The fate of groundwater that recharges beneath the historical MRSAs was determined by conducting particle tracking. The particle traces at the end of construction are presented on Map 16 assuming no contact water collection system operating. The inclusion of a contact water collection system would decrease the groundwater discharge from these areas. The particle traces were used to quantify the inflow rates and travel times to the open pit and discharge to surface water features from each historical MRSA and are presented in Table 5-4.

Table 5-4 Predicted Groundwater Discharge Rates (m^3/s) from Historical Mine Rock Storage Areas to Receiving Environment during Construction

Mine Rock Storage Area	Receptor	Discharge (m^3/s)	Travel Time (years)		
			Minimum	Mean	Maximum
Historical North MRSA	Interceptor Wells	1.1×10^{-5}	0.06	0.81	1.43
Historical South MRSA	East Pit	1.8×10^{-5}	0.01	1.09	>2.0
	Wendy Pit	1.2×10^{-5}	0.02	0.73	>2.0

Groundwater recharge from beneath the historical north MRSA is captured by the interceptor wells with a mean advective travel time of less than 1 year. Groundwater recharge from beneath the historical south MRSA discharges to the East Pit or Wendy Pit, with a mean advective travel time of 1 year, or less.

5.3 OPERATION

The groundwater model was subsequently modified from the construction phase to simulate the effects of the Project during operation on groundwater levels and flow and the fate of groundwater originating from the historical and new MRSAs during operation. As part of these simulations, the model was used to predict groundwater inflows to the open pit and to evaluate the flow paths and groundwater discharge rates to receptors for recharge that originates from the MRSA.

5.3.1 Model Setup

Starting with the calibrated groundwater flow model and modifications completed for construction, the following additional modifications were completed:

- development and dewatering of the open pit
- variations in recharge rates related to the development of the MRSA
- reduction of footprint of the historical MRSAs as open pit develops

The modifications are discussed below for each Project component.

5.3.1.1 Open Pit Dewatering

To evaluate the effects of groundwater inflows to the open pit the calibrated groundwater flow model was modified to include the extents and depths of the open pit for two specified stages of pit development during operation:

- Mine Year 2: representing the intermediate development stage of the open pit.
- Mine Year 5: representing the ultimate extent of the open pit development at the completion of mining at the Gordon site.

Model nodes that were intersected by the walls or floor of the open pit were identified and assigned as a seepage face boundary condition in the model. Model nodes that were located above the seepage face nodes within the footprint of the open pit were set as inactive.

The hydraulic conductivity of the seepage face nodes was adjusted on a monthly basis to reflect the reduced hydraulic conductivity based on freezing and thawing of the seepage face. The hydraulic conductivity was determined using the heat transport functionality of FEFLOW with the FTM plugin. Simulations of the freezing and thawing were used to determine the changes in hydraulic conductivity predicted based on the average monthly air temperatures. Due to the additional computational burden of running the model in heat and transport mode, the simulation of effects of freezing on dewatering were conducted with only the flow components in FEFLOW, using the variable hydraulic conductivity at the pit face due to freezing as inputs that was determined using the FTM plugin.

Each of the three open pit development stages (i.e., Mine Year -2 (construction), Mine Year 2, and Mine Year 5) were simulated in the model as separate transient model runs, with the results of the previous runs used as the starting condition of the next run. Year -2 model run, presented in Section 5.2.2, represents the dewatering of the existing East and Wendy pits. An intermediate pit stage at half the life of the mine (Mine Year 2) was used as the next condition and the ultimate pit stage at the end of mine life (Mine Year 5) used as the final condition.

5.3.1.2 Groundwater Interceptor Wells

The groundwater interceptor wells installed during construction, as presented in Section 5.2.1.2, remain in place during operation to control inflows to the open pit due to a high permeability zone in the shallow bedrock associated with the East and Wendy faults (Map 9). The pumped water from the interceptor wells was assumed to be discharged to the nearest lake (Gordon or Farley). The effects of the operation of the interceptor wells during the operation phase are evaluated using the calibrated groundwater flow model modified to represent the interceptor wells pumping at 0.014 m^3/s each for the top 50 m of bedrock using a specified flux boundary condition.

5.3.1.3 Mine Rock Storage Areas

In addition to the two historical MRSAs, the Project includes a new MRSA for the collection of surplus mine rock (Map 3). Recharge through the MRSA has the potential to affect groundwater quality and as a result the model was used to determine the discharge location and flux of water recharging the groundwater flow system from beneath the MRSA. To provide a conservative estimate of the groundwater discharge originating from the MRSA, groundwater flow simulations were conducted without the contact water collection systems.

The structure of the MRSA was not added explicitly to the groundwater flow model. As the MRSA is placed on top of the existing ground surface, the MRSA was represented in the model by adjusting the groundwater recharge within the footprint of the MRSA. The groundwater recharge within the footprint of the MRSA was estimated using the site-wide water balance, which is presented in the Water Balance and Water Quality Model (Stantec 2020d).

The infiltration rate into the MRSA considers losses due to evaporation and surface runoff and was predicted to be approximately 25% of the total precipitation. As the MRSA is developed, it will take time before the MRSA reaches saturation and the precipitation infiltrating into the pile will equal the volume of water leaving the base of the pile (e.g., steady-state conditions). Infiltration that reaches the base of these piles is expected to either flow laterally along the ground surface and report as seepage at the toe of the pile (toe seepage) or recharge the underlying groundwater flow system based on the permeability of the underlying soils.

To determine the proportion of infiltration that recharges the groundwater flow system beneath the new MRSA, a SEEP/W model was used in conjunction with the groundwater flow model. The SEEP/W model was used to determine the amount of seepage that is collected in toe seepage drains (i.e., lateral seepage from surface runoff or from the waste rock/native overburden interface). The lateral drainage from within the waste rock pile was not allowed to exceed the calibrated recharge rates in the groundwater flow model. The average recharge rate to the groundwater flow system under the new MRSA was 120 mm/yr.

The groundwater flow model was used to determine the discharge location and flux of water recharging the groundwater flow system from beneath the new MRSA, using the method described for the historical MRSAs in Section 5.1.1.

5.3.2 Results

5.3.2.1 Open Pit Dewatering

The predicted pumping rates to maintain a dewatered seepage face for the three model runs were used to interpret groundwater pumping rates over the life-of-mine (LOM), which are presented in Figure 5-2. These pumping rates only consider inflows to the open pit due to groundwater and do not consider surface water runoff or precipitation inflows. As dewatering progresses, the average annual groundwater inflow rate increases from 0.023 m^3/s at the end of the construction period to 0.037 m^3/s at end of operation.

The simulated water table at the end of mine life is presented in Map 17. Changes in the water table elevation due to dewatering of the interceptor wells and the open pit are evident primarily in the area of the open pit.

The drawdown or change in water table elevation due to dewatering of the open pit at end of LOM in comparison to baseline conditions, is shown on Map 18. Dewatering of the open pit will lower the water table by up to 1.0 m that extends over an area of approximately 1,200 m from the open pit, increasing to more than 10 m within 600 m of the open pit. The induced infiltration of surface water to the shallow overburden and bedrock limits the extent of the drawdown.

Table 5-5 presents the comparison of groundwater discharge rates with effects of the dewatering at the end of the operation period (i.e., Mine Year 6). As shown in Table 5-5, Gordon, Farley, and Marie Lakes are predicted to shift from gaining groundwater to losing groundwater, as was observed during construction. The water pumped from the interceptor wells will be returned to Gordon and Farley lakes during operations to offset a reduction in groundwater discharge. For Marie Lake, the changes to the groundwater flow is relatively small compared to the overall anticipated flow rate and are not anticipated to affect water levels in the lakes.

The changes to groundwater discharge rates for remaining lakes and watercourses are relatively small (generally less than 0.001 m^3/s) compared to the overall anticipated flow rates in the surface water features.

Table 5-5 Estimated Groundwater Discharge to Watercourses and Lakes at End of Operation (m^3/s)

NOTES:
1. Positive value represents flow from groundwater to surface water
   Negative value represents flow from surface water to groundwater

5.3.2.2 Sensitivity of Open Pit Dewatering to Bedrock Hydraulic Conductivity

The calibration of the groundwater model was based on the fit of water levels by adjusting the assumed uniform hydraulic conductivity of hydrostratigraphic units. It is noted from Table 4-3 that the hydraulic conductivity range for the shallow bedrock has the highest observed range of the hydrostratigraphic units, and that the hydraulic conductivity of the shallow bedrock is highest of the bedrock units (Figure 3-1). As the groundwater flow at the site is expected to occur dominantly through the shallow bedrock, a sensitivity analysis was conducted to assess the effects of adjusting the hydraulic conductivity within the shallow bedrock on the expected inflows to the open pit. This included both the shallow bedrock and faulted shallow bedrock zones, shown on Map 9.

The sensitivity analysis consisted of two scenarios where the hydraulic conductivity of the shallow bedrock layers was adjusted. The details of the analysis are presented in Table 5-6. The results are compared against the average annual end of mine (EOM) inflow rates to the open pit as presented above as a base case.

Table 5-6 Sensitivity Analysis of Groundwater Inflows to Bedrock Hydraulic Conductivity – End of Operation

Scenario	Hydraulic Conductivity (m/s)		Total Pit Inflow (m^3/s)	Total Well Extraction (m^3/s)	Total Dewatering Rate (m^3/s)	Change from Baseline (%)
	Shallow Bedrock	Faulted Shallow Bedrock				
Base Case	1.2×10^{-6}	1.2×10^{-5}	0.021	0.201	0.222	-
1	1.2×10^{-5}	1.2×10^{-5}	0.057	0.224	0.281	27%
2	1.2×10^{-7}	1.2×10^{-5}	0.020	0.197	0.217	-2%

3	1.2×10^{-6}	1.2×10^{-4}	0.262	0.213	0.475	114%
4	1.2×10^{-6}	1.2×10^{-6}	0.026	0.091	0.117	-47%

As shown on Table 5-6, the total inflow to the open pit is sensitive to the value of hydraulic conductivity assigned to the faulted shallow bedrock, particularly as the hydraulic conductivity increases. Varying the hydraulic conductivity of the shallow bedrock by two orders of magnitude resulted in less than a 30% change in the total estimated dewatering required for the open pit and interceptor wells. However, varying the faulted bedrock hydraulic conductivity by the same range resulted in much larger changes to the total dewatering rate, from 47 to 114% compared to baseline. It is noted that increasing the hydraulic conductivity of the shallow bedrock or faulted shallow bedrock by an order of magnitude would also have a detrimental effect on the calibration of the model. Therefore, the hydraulic conductivity values determined during the calibration of the model are considered representative and are carried forward in the analyses.

5.3.2.3 Mine Rock Storage Areas

The fate of groundwater that recharges beneath the MRSAs (historical and new) was determined by conducting particle tracking. The particle traces at the EOM are presented on Map 19 assuming no contact water collection system operating. This assumption provides a conservative assessment of potential groundwater discharge to the receiving environment. The inclusion of the contact water collection system would decrease the groundwater discharge from these areas. The particle traces were used to quantify the inflow rates and travel times to the open pit and discharge to surface water features from each MRSA and are presented in Table 5-7.

Table 5-7 Predicted Groundwater Discharge Rates (m^3/s) from Mine Rock Storage Areas to Receiving Environment at End of Operation

Mine Rock Storage Area	Receptor	Discharge (m^3/s)	Travel Time (years)			Discharge Arriving within 300 years (m^3/s)
			Minimum	Mean	Maximum	
Historical North MRSA	Interceptor Wells	1.1×10^{-5}	12.3	18.9	30.1	1.1×10^{-5}
Historical South MRSA	Open Pit	9.1×10^{-5}	<0.1	3.4	17.2	9.1×10^{-5}
New MRSA	Open Pit	6.1×10^{-4}	29.7	321	2,022	$4.0\text{x}10^{-4}$
	Susan Lake	1.9×10^{-5}	545	954	2,615	Negligible

Groundwater recharge from beneath the historical north MRSA discharges to the interceptor wells with a mean advective travel time of less than 19 years. Groundwater recharge from beneath the historical south MRSA discharges to the open pit with a mean advective travel time of less than 4 years. The total recharge from both of these areas are less than predicted during construction, as the open pit encroaches on these areas, decreasing the size of the historical MRSAs. The majority (i.e., 97%) of the recharge from the new MRSA, which is located farther from the open pit than the historical MRSAs, discharges to open pit with a mean advective travel time of approximately 300 years. The balance of recharge from the new MRSA discharges to the Susan Lake with a mean advective travel time of approximately 900 years.

Given the long flow paths for seepage from the new MRSA, the proportion of seepage arriving at a receiver within 300 years is provided for reference in Table 5-7. Three hundred years travel time was used as a threshold for input to the water balance model (Stantec 2020d), which had a 300-year run time.

5.4 CLOSURE

The groundwater model was subsequently modified from the operation phase to simulate the effects of the Project on groundwater levels and flow and the fate of groundwater originating from the historical and new MRSAs during closure. As part of these simulations the model was used to predict groundwater inflows to the open pit as the pit fills and to evaluate the flow paths and groundwater discharge rates to receptors for recharge that originates from the MRSAs.

5.4.1 Model Setup

Starting with the calibrated groundwater flow model and modifications completed for the end of operation, the following additional modifications were completed:

- Filling of the open pit
- Decreased pumping from groundwater interceptor wells

The modifications are discussed below for each Project component.

5.4.1.1 Open Pit Filling

The filling of the open pit during closure was simulated by removing the boundary conditions representing the open pit during operation and predicting the inflow rate and water level position over time in the open pit.

5.4.1.2 Groundwater Interceptor Wells

The groundwater interceptor wells installed in the high permeability zone in the shallow bedrock associated with the East and Wendy faults (Map 9) were assumed to continue to operate during the first stages of closure, as discontinuing the pumping was predicted to dewater Gordon Lake. Pumping of the interceptor wells decreased with time as the pit level stage was increased, so that the pumping did not interfere with the water level in the open pit. The pumped water from the interceptor wells was assumed to be discharged to the nearest lake (Gordon or Farley).

5.4.2 Results

5.4.2.1 Open Pit Filling

The rate of groundwater inflow for the open pit to fill after the end of mining activities is presented in Figure 5-3. The groundwater inflow rate increases from 0.037 m^3/s at a pit lake elevation of 126 m AMSL, increasing to a peak rate of 0.076 m^3/s after the interceptor wells begin to decrease their pumping rates at a pit lake elevation of 256 m ASML, and decreasing to 0.0001 m^3/s at a final pit lake level of 315 m AMSL.

The groundwater inflow rates to the open pit presented on Figure 5-3 were incorporated into the water balance (Stantec 2020d) to evaluate the overall time to fill the open pit during closure, considering all sources of water inputs.

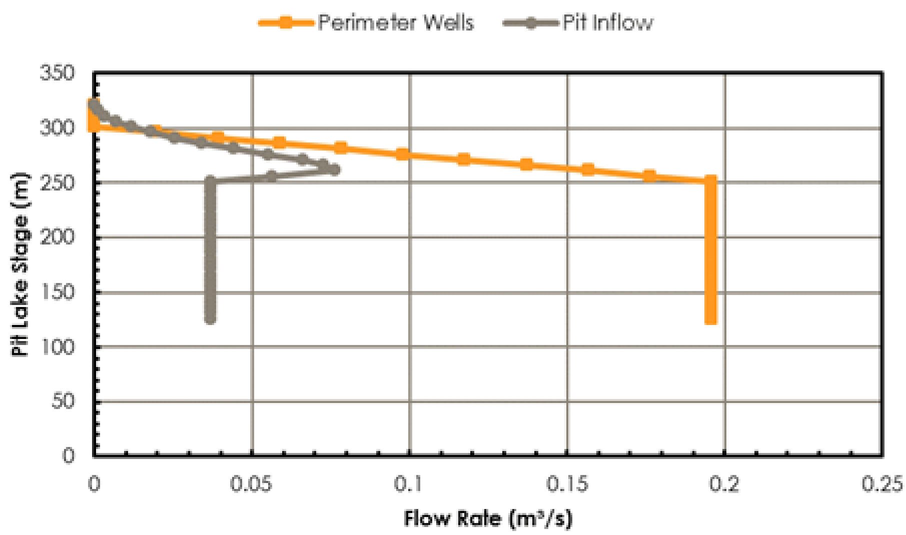

Figure 5-3 Pit Filling Rates During Closure

Table 5-8 presents the comparison of baseline groundwater discharge rates with effects of the pit lake on the surface water flows at closure (i.e., after the pit lake is full). As shown in Table 5-8, the groundwater flows to the receptors are predicted to return to near baseline rates (within 0.001 m^3/s of baseline conditions) once the pit is full. The largest change in baseline to closure groundwater discharge rates is predicted at Marie Lake, which is predicted to contribute 0.0007 m^3/s more flow in closure than during baseline conditions.

Table 5-8 Estimated Groundwater Discharge (m^3/s) to Watercourses and Lakes under Closure Conditions

NOTES:
1. Positive value represents flow from groundwater to surface water
   Negative value represents flow from surface water to groundwater

The water elevation contours and drawdowns at the end of the closure period (i.e., when the pit is full), are presented on Maps 20 and 21, respectively. As shown, at the end of closure, the water table is predicted to return to near baseline conditions, although a small area between the open pit and Farley Lake are predicted to have groundwater levels about 0.5 m lower than baseline.

5.4.2.2 Mine Rock Storage Areas

The fate of groundwater that recharges beneath the MRSAs (historical and new) was determined by conducting particle tracking. The particle traces at closure are presented on Map 22 assuming no contact water collection system operating. The inclusion of the contact water collection system would decrease the groundwater discharge from these areas. The particle traces were used to quantify the inflow rates and travel times to the open pit and discharge to surface water features from each MRSA and are presented in Table 5-9.

Table 5-9 Predicted Groundwater Discharge Rates (m^3/s) from Mine Rock Storage Areas to Receiving Environment at Closure (Pit Full)

Mine Rock Storage Area	Receptor	Discharge (m^3/s)	Travel Time (years)			Arriving within 300 years (m^3/s)
			Minimum	Mean	Maximum	
Historical North MRSA	Gordon Lake	1.2×10^{-5}	133	252	541	8×10^{-6}

Table 5-9 Predicted Groundwater Discharge Rates (m^3/s) from Mine Rock Storage Areas to Receiving Environment at Closure (Pit Full)

Mine Rock Storage Area	Receptor	Discharge (m^3/s)	Travel Time (years)			Arriving within 300 years (m^3/s)
			Minimum	Mean	Maximum	
Historical South MRSA	Pit Lake	4.1×10^{-5}	<1	1,578	16,931	3.5×10^{-5}
	Gordon Lake	2.3×10^{-7}	214	214	214	2.3×10^{-7}
	Farley Lake	3.7×10^{-5}	1.2	829	9,242	2.4×10^{-5}
New MRSA	Pit Lake	2.6×10^{-4}	1,153	6,010	24,941	Negligible
	Gordon Lake	4.6×10^{-5}	821	1,048	1,438	Negligible
	Farley Lake	1.3×10^{-4}	374	2,894	10,517	Negligible
	Susan Lake	2.1×10^{-4}	193	827	4,110	8.7×10^{-6}

Groundwater recharge from beneath the historical north MRSA discharges to Gordon Lake with a mean advective travel time of about 250 years. Groundwater recharge from beneath the historical south MRSA discharges fairly equally to the pit lake, with a mean advective travel time of about 1,500 years, or Farley Lake, with a mean advective travel time of about 830 years. Forty percent of the recharge from the new MRSA discharges to the pit lake with a mean advective travel time of approximately 6,000 years. The balance of recharge from the new MRSA discharges to Susan Lake (33%), Farley Lake (20%), or Gordon Lake (7%), with mean advective travel times in excess of 800 years.

Given the long flow paths for seepage from the historical and new MRSA, the proportion of seepage arriving at a receiver within 300 years is provided for reference in Table 5-9. Three hundred years travel time was used as a threshold for input to the water balance model (Stantec 2020d), which had a 300-year run time.

5.4.2.3 Sensitivity of Groundwater Discharge to Recharge

A sensitivity analysis was conducted to assess the potential effect of an increase or decrease in the future recharge rate on groundwater discharge to the receiving environment. The sensitivity analysis consisted of two scenarios where the recharge was adjusted as a 25% increase and a 25% decrease from the calibrated, baseline recharge value for each recharge zone. Table 5-9 presents the recharge values used in the sensitivity scenarios compared to the baseline recharge value.

Table 5-10 Sensitivity Analysis Recharge Scenarios

Scenario	Recharge Zone 1 (mm)	Recharge Zone 2 (mm)	Recharge Zone 3 (mm)
Baseline (calibration)	16	33	5
25% decrease	12	24.8	3.8
25% increase	20	41.3	6.3

Notes:
Recharge Zone 1 includes historical MRSA, organics, and sand diamicton hydrostratigraphic units
Recharge Zone 2 includes glaciolacustrine offshore and glaciolacustrine nearshore hydrostratigraphic units
Recharge Zone 3 includes shallow bedrock and faulted shallow bedrock hydrostratigraphic units.

The predicted groundwater discharge to the receiving environment for closure are presented in Table 5-10 for the baseline recharge rate, the 25% increase, and 25% decrease in recharge rate. The relative percent difference in groundwater discharge to watercourses and lakes is less than 8%, and generally less than 3%, when comparing the 25% change in recharge with the calibrated model recharge for the closure scenario. The results indicate the groundwater discharge to watercourses and lakes is relatively insensitive to variations in recharge.

Table 5-11 Sensitivity Analysis of Groundwater Discharge to Recharge – Closure (Pit Full)

Watercourse	Estimated Groundwater Discharge (m^3/s) to Watercourses and Lakes			
	Baseline[1]	Closure[1]	Closure 25% Decrease in Recharge[1]	Closure 25% Increase in Recharge[1]

Notes:
1. Positive value represents flow from groundwater to surface water
   Negative value represents flow from surface water to groundwater

5.5 PREDICTION CONFIDENCE

The approach used in model simulations completed for this Project was to incorporate conservative assumptions for predicting effects that may result from the Project. This report presents the assumptions made in developing these conservative predictions and discusses the high-level confidence of these predictions.

Groundwater recharge rates at the new MRSA and the historical MRSAs to the receiving environment are conservatively "over predicted" in two ways. First, the results from modelling conducted without the presence of the seepage collection system are used to predict groundwater flows to the receiving environment and to inform the environmental effects assessment. Second, all of the recharge applied within the MRSAs over the life of the mine is assumed to be carried through to the final receptors. In reality, a portion of seepage from the MRSAs may be intercepted by the seepage collection ditches and/or reduced due to design of the MRSA (e.g., additional design to enhance runoff).

The groundwater flow modelling was conducted using a model calibrated to water levels and baseflow targets to establish baseline conditions. Predictions made using the model are based on several conservative assumptions to reduce the influence of uncertainty in the predictions. Therefore, the confidence in the predictions made using the model is considered high.

6.0 CONCLUSIONS

Hydrogeology modelling was conducted to identify changes to groundwater levels and flow pathways to inform the assessment of potential effects of the LLGP on groundwater and surface water resources at the Gordon site. The modelling was conducted using FEFLOW and was calibrated to baseline conditions within acceptable industry standards.

The construction and operation of the open pit will require the open pit to be dewatered. This will also include dewatering from a series of interceptor wells installed between the pit and Gordon and Farley lakes that will be used to mitigate pit inflows. The dewatering of the open pit and pumping from the interceptor wells will result in the drawdown of the water table by up to 1 m over an area extending approximately 1,200 m around the open pit. As dewatering progresses, the average annual groundwater inflow rate increases 0.023 m^3/s to the historical pits at the end of construction to 0.037 m^3/s to the open pit at the end of operation.

The dewatering of the open pit and interceptor wells will also result in changes to groundwater discharge conditions in lakes and watercourses located near the open pit. Changes in groundwater discharge to most surface water features will remain similar to baseline conditions throughout operations, with Gordon and Farley lakes shifting from gaining to losing as a result of dewatering operations. However, these effects will be mitigated by using the groundwater interceptor wells to return water to the lakes.

Groundwater discharge to surface water features associated with the MRSAs represents a minor component of the overall surface water flow systems. The modelling results will be considered in the assessment of potential effects on the receiving environment.

9.0 LIMITATIONS

This Technical Modelling report entitled Lynn Lake Gold Project Hydrogeology Assessment: Gordon Site was prepared by Stantec Consulting Ltd. ("Stantec") for the account of Alamos Gold Inc. (the "Client") to support the approvals and permitting process for the Lynn Lake Gold Project in Lynn Lake, Manitoba. In connection thereto, this document may be reviewed and used by the federal and provincial government agencies participating in the approvals and permitting process in the normal course of their duties; and stakeholders may provide comment as part of the regulatory approvals process. Except as set forth in the previous sentence, any reliance on this document by any third party for any other purpose is strictly prohibited. The material in it reflects Stantec's professional judgment in light of the scope, schedule and other limitations stated in the document and in the contract between Stantec and the Client. The opinions in contents of the document are based on conditions and information existing at the time the document was published and do not take into account any subsequent changes. In preparing the document, Stantec did not verify information supplied to it by others. Any unauthorized use that a third party makes of this document is the responsibility of such third party. Such third party agrees that Stantec shall not be responsible for costs or damages of any kind, if any, suffered by it or any other third party as a result of decisions made or actions taken based on unauthorized use of this document.

1.0 INTRODUCTION

The Lynn Lake Gold Project (LLGP; or "the Project") consists of two primary deposit sites, which are both located near Lynn Lake, Manitoba: the 'Gordon' site and the 'MacLellan' site. Alamos Gold Inc. (Alamos) intends to construct (redevelop), operate and eventually close/reclaim open pit gold mines at both these historical mine sites. The Gordon site is located approximately 55 kilometres (km) east of Lynn Lake, Manitoba (by vehicle), and the MacLellan site is located approximately 8 km northeast of Lynn Lake (by vehicle) (Map 1, Appendix A). Lynn Lake is located approximately 820 km northwest of Winnipeg.

This Hydrogeology Technical Modeling Report (TMR) for the MacLellan site has been prepared to assess the potential effects of the construction, operation, and closure phases of the Project on groundwater resources and the consequent indirect effects on surface water resources at the MacLellan site. The TMR considers the MacLellan site components of the Project, baseline data collected for the Project since 2015, and comments received from agencies, Indigenous communities, and other stakeholders.

To evaluate the effects of the Project, a groundwater flow model has been developed for the MacLellan site to provide estimates of:

- Changes in groundwater levels (drawdown), including changes to water table position and groundwater flow, due to dewatering of the MacLellan open pit.
- The time to fill the MacLellan open pit from groundwater inflow for use as an input to the water balance modelling conducted for the Project.
- Groundwater flow and discharge to wetlands, creeks and lakes under baseline, operation, and closure.
- Groundwater recharge and flow pathways from historical mine rock piles, overburden storage area, TMF, and MRSA developed for the Project under operation and closure.

This TMR, and a companion TMR conducted for the Gordon site (Stantec 2020b), form part of the supporting documentation for the Environmental Impact Statement (EIS)/Environmental Assessment (EA) completed for the Project.

2.0 BACKGROUND

This section provides an overview of the existing conditions that were used as background for the MacLellan site hydrogeology model development. More detailed information is presented in the following reports:

- Hydrogeology Baseline Technical Data Report (Stantec 2017c)
- Hydrology Baseline Technical Data Report (Stantec 2017b)
- Hydrogeology Technical Data Report: Validation Report (Stantec 2020a)
- Hydrology Baseline Technical Data Report: Validation Report (Stantec 2020c)

2.1 HISTORICAL MINING OPERATIONS

Historical mining operations at the MacLellan site consisted of the development of an underground mine to a depth of 448 m with five operating levels (Map 2) and a MRSA. The following is a summary of the historical mining operations described by Tetra Tech (2013).

The underground mine was active between 1986 and 1989 and produced 144,000 oz of gold and 432,000 oz of silver from a production rate of about 900 to 1,200 tpd. The shaft was first sunk in 1969 and extended to a depth of 149 m, which was then deepened to 259 m between 1980 and 1985. In 1986, the shaft was deepened to 448 m and production commenced. Ramp access from surface extends to 420 m.

The mine operated under a license that allowed for the discharge of mine water and sewage-plant effluent into polishing ponds and a marshy area adjacent to the Keewatin River. Mining continued through to 1989 when production ceased due to high operating costs and falling gold prices. From 1989 to 2000, additional drilling, trenching over crown pillar, geological mapping, and channel sampling was completed. In 2000, the mine was allowed to flood. The site has been in a state of 'care and maintenance' since 1989 with very little reclamation. Existing historical mine infrastructure includes the head frame, hoist house, maintenance building, and core shack and an historical MRSA. The historical MRSA shown on Map 2 contains surplus mine rock from historical mining operations at the MacLellan site.

2.2 CLIMATE

The climate and meteorology of the MacLellan site are detailed in the Climate and Meteorology Baseline Technical Data Report (Stantec 2017a). The Lynn Lake area has a climate typical of Northern Manitoba. The nearest permanent weather monitoring stations are Environment and Climate Change Canada stations 5061645 and 5061649, located at the Lynn Lake Airport. Climate normals (1981-2010) average temperature, precipitation, total rainfall, and total snowfall statistics for the Lynn Lake Airport are summarized in Table 2-1.

Table 2-1 Climate Normals (1981 to 2010) Statistics at Lynn Lake Airport

Month	Monthly Average Temperature (°C)	Average Total Precipitation (mm)	Average Total Rainfall (mm)	Average Total Snowfall (cm)
January	-24	20	0.2	28
February	-20	16	0.1	24
March	-13	20	1.4	25
April	-3.1	24	4.5	24
May	5.6	37	27	10
June	13	62	61	1.3
July	16	85	85	0.1
August	15	69	69	0.1
September	7.7	61	57	3.5
October	-0.6	38	12	31

Month	Monthly Average Temperature (°C)	Average Total Precipitation (mm)	Average Total Rainfall (mm)	Average Total Snowfall (cm)
November	-13	27	0.8	36
December	-21	19	0.1	26
Annual	-3.2	478	318	208

The average monthly temperature is normally above freezing from May to September. The annual total precipitation for the region is 478 mm using the 1981 to 2000 climate normals, with 34% occurring as snow and 66% as rain. July typically receives the most monthly precipitation and February the least.

2.3 PHYSIOGRAPHY, TOPOGRAPHY, AND DRAINAGE

The MacLellan site is surrounded by vegetated land, forest cover, scattered lakes, watercourses, and wetlands and is located within areas of discontinuous permafrost cover.

Regional topography around the MacLellan site slopes from a high of 375 m above mean sea level (AMSL) in the west and northwest to a low of 325 m AMSL in the southeast (Map 4). The ground surface is characterized as hummocky with steeply sloping rocky ridges that may extend 30 m to 60 m above lakes and peat-filled depressions. Surface water features and peat deposits generally occupy the topographic lows.

2.4 REGIONAL GEOLOGIC CONTEXT

A summary of the regional geology is provided below. Additional information on the regional and local geology is provided in the Hydrogeology Baseline Technical Data Report (Stantec 2017c) and subsequent validation report (Stantec 2020a).

2.4.1 Overburden Geology

The regional surficial geology has been mapped by the Geological Survey of Canada as shown on Map 5 (Kaszycki et al. 2008). During the Late Wisconsinan period, the advance of the Keewatin ice centre (part of the Laurentide Ice Sheet) deposited glacial diamicton (diamicton) derived from the crystalline bedrock of the Canadian Shield. Meltwaters, resulting from the retreat of glacial ice, eroded and cut through the various glacial deposits and resulted in deposition of glaciofluvial sediments that are typically stratified and sorted to varying degrees. As the ice retreated, glacial Lake Agassiz was formed and resulted in the deposition of glaciolacustrine laminated silt and clay.

2.4.2 Bedrock Geology

The bedrock geology of the area has been described in detail by the Manitoba Geological Survey. The Gordon and MacLellan sites are located within part of the Lynn Lake greenstone belt, which is located in the Churchill Structural Province of the Canadian Shield. Map 6 presents the regional bedrock geology. The Lynn Lake greenstone belt is comprised of metamorphosed volcanic rocks of the Wasekwan Group, metamorphosed sedimentary rocks of the Sickle Group, and plutonic intrusions. The Lynn Lake greenstone belt trends west to east and extends 130 km from the La Ronge greenstone belt in Saskatchewan (MEM 1986). Structural processes altered the Lynn Lake greenstone belt into two belts (north belt and south belt), that are separated by felsic intrusions (Beaumont-Smith and Böhm 2003). The north and south belts differ by stratigraphic sequences, chemistry, and structure (MEM 1986).

The Gordon and MacLellan sites are located within the north belt, which is characterized as a north-dipping homocline comprised of rhyolite, overlain by andesite and sedimentary rocks, and an upper unit of basaltic rocks (MEM 1986). The north belt includes the unique stratigraphic sequence known as the Agassiz Metallotect (also termed “Rainbow Trend”) (Map 6), which consists of picritic flows, iron formation, and felsic volcanic rocks. The metallotect hosts the gold deposits of the Gordon and MacLellan sites. South of the properties lies the south belt, which consists of volcanic and sedimentary rocks and the east-west trending structural feature identified as the Johnson Shear Zone (Map 6). In some areas, these weathered shear zones may have been preferentially eroded because of the orientation of the shear zone relative to the direction of ice movement and the competence of the weathered bedrock in the shear zone relative to the surrounding bedrock units (Machibroda Engineering 1988).

The MacLellan site has three mineralized deposits, the Rainbow-Dot Deposit, the MacLellan Deposit, and the Nisku Deposit. The three deposits are located south of a major east-west trending North Shear Zone (NSZ) fault, which strikes southeast (065°) and dips 75° to 85 to the north (Map 4).

3.0 CONCEPTUAL MODEL

3.1 MODELLING APPROACH

The development of a conceptual model is the fundamental first step in the preparation of a numerical groundwater model. The conceptual model combines the available hydrologic and hydrogeologic data from a site and allows for the interpretation of the hydrostratigraphy and boundary conditions so they can be entered into a numerical groundwater flow model. The general approach used to develop the conceptual and numerical model was to add complexity as warranted by the available data to achieve the objectives of the numerical modelling (see Section 1.1).

The development of the conceptual model was facilitated by the use of the geologic modelling software, Leapfrog Hydro® Version 2.5.2. The software was used to create three-dimensional (3D) volumes for each of the defined hydrostratigraphic units in the conceptual model. Inputs for volume generation included wireframes for the ground surface topography, structural features, historical underground workings, as well as contact points for the various lithologies defined from borehole and outcrop data. The conceptual model built using Leapfrog Hydro® software can be transferred directly to popular hydrogeology modelling software, including MODFLOW and FEFLOW.

3.2 CONCEPTUAL MODEL BOUNDARIES

The conceptual model boundaries were defined to coincide with or extend beyond the proposed limits for the groundwater flow model. Natural hydrologic and hydrogeologic boundaries such as watershed boundaries and surface water bodies were used to define the lateral extent of the conceptual model. The boundaries of the conceptual model correspond with the study area illustrated on Map 3. The model boundaries coincide with watershed boundaries as defined in the Hydrology Baseline Technical Data Report (Stantec 2017b). The boundaries of the conceptual model were constrained vertically by ground surface topography and extended 50 m below the base of the proposed open pit.

The conceptual model and groundwater flow model were developed based on the geologic and hydrogeologic data presented in the Hydrogeology Baseline Technical Data Report (Stantec 2017c). The data collected following this date and included in the groundwater data validation report (Stantec 2020a) were reviewed to confirm the model. The model was determined to not require edits based on the additional data collected.

3.3 HYDROSTRATIGRAPHY

The following hydrostratigraphic units are interpreted within the study area and are incorporated into the conceptual model. Details for each hydrostratigraphic unit are summarized in Sections 3.3.1 to 3.3.5:

- Historical Mine Rock
- Organics
- Glaciolacustrine
- Sand Diamicton
- Bedrock

Cross-sections depicting the geological interpretation of the hydrostratigraphic units across the study area are shown on Maps 7 to 9. The cross-section locations are presented on Map 4. Additional description of the hydrostratigraphic units is presented below, including references to monitoring well locations, where appropriate.

3.3.1 Historical Mine Rock Storage Area

A historical MRSA, identified on Map 2, contains surplus mine rock from historical mining operations at the MacLellan site. This historical MRSA was not capped or covered following the closure of historical mining activities. Hydraulic testing of the historical mine rock was not completed due to their expected high hydraulic conductivity values and limited extent below the water table. Typical testing methods are difficult to perform under these conditions. Based on the grain size and material descriptions, hydraulic conductivity values for historical mine rock were assumed to vary between 1×10^{-3} and 1×10^{-2} metres per second (m/s) during model calibration. This range is consistent with the reported hydraulic conductivity for gravel (Freeze and Cherry 1979).

3.3.2 Organics

Organic deposits in the form of fibric peat and topsoil were observed at ground surface throughout the study area. Fibric peat is the least decomposed type of peat and generally consists of greater than 30% organic material or greater than 17% organic carbon. Topsoil was observed in upland portions of the landscape and was characterized as mineral soil with minor enrichment of organic material. Typical thicknesses were less than 1 m, but accumulations of up to 3.6 m were observed in low-lying areas such as at monitoring well GBHM-22. Organic deposits were found underlying surficial fill in boreholes completed along the access road.

Hydraulic testing of the organic deposits was not completed due to their shallow nature and thickness. Hydraulic conductivity values from literature cover a wide range and are dependent on the texture of the sediments composing the organic deposit. Based on the geology and material descriptions, hydraulic conductivity values for organic deposits were assumed to vary between 1×10^{-8} and 1×10^{-5} m/s during model calibration (Fetter 2000).

3.3.3 Glaciolacustrine

Glaciolacustrine deposits were observed across the study area at either ground surface or underlying organic deposits. The glaciolacustrine deposits were discontinuous (Maps 8 and 9). The glaciolacustrine deposits consisted of nearshore coarse-grained deposits and offshore fine-grained deposits. Nearshore and offshore deposits were generally observed to grade laterally between the two units; however, in some areas the units were interlayered (Maps 8 and 9). Therefore, these units were conceptualized to be one hydrostratigraphic unit.

Hydraulic conductivity estimates from slug tests conducted in the glaciolacustrine nearshore deposits ranged from 1×10^{-7} to 6×10^{-5} m/s.

3.3.4 Sand Diamicton

Discontinuous deposits of sand diamicton were observed throughout the MacLellan site, consistent with the interpretation that the unit has been eroded by meltwaters associated with the retreat of glacial ice. When present, sand diamicton overlaid bedrock and was overlain by glaciolacustrine or organic deposits. Sand diamicton was observed in areas primarily to the northeast of the proposed open pit. The thickness of the sand diamicton generally ranged from less than 1 m to greater than 28 m (at monitoring well GBHM-14, Map 4). The sand diamicton was generally observed to occupy bedrock lows such as at monitoring wells GBHM-01, GBHM-07, and GBHM-14 (Map 4), where the thickness of the unit was observed to be greatest. Generally, the sand diamicton overlaid bedrock except in the northeast, where it overlaid glaciofluvial deposits.

Hydraulic conductivity estimates from slug tests conducted in the sand diamicton deposits ranged from 4×10^{-7} to 6×10^{-5} m/s.

3.3.5 Bedrock

Bedrock was defined as a continuous unit throughout the study area. The top of bedrock surface described in Stantec (2017c; 2020a) was interpreted from the boreholes and test pits installed at the MacLellan site, including boreholes drilled for exploration and condemnation purposes. The bedrock topography was interpreted to follow a similar trend to ground surface topography. Bedrock was observed near surface in areas associated with topographic highs and at depths up to 10 m below ground surface (BGS) associated with topographic lows, except in areas where bedrock depressions or valleys were observed. A bedrock depression or valley was observed at GBHM-01 (Map 4) located on the eastern edge of the proposed open pit and GBHM-05 located between the proposed open pit and Keewatin River in the area of the NSZ fault. Bedrock was encountered at 17.5 m BGS (317.5 m AMSL) at monitoring well GBHM-01 and at 15.8 m BGS (317.5 m AMSL) at monitoring well MWM-05.

A deep bedrock valley located along the northern edge of Minton Lake was identified from borehole logs for GBHM-14 and MWM-03 (Map 4). The orientation and extent of this bedrock valley is unknown but appears to be filled with sand diamicton that has been eroded and replaced by extensive glaciofluvial deposits. It is likely the valley was formed by erosion of the bedrock by glacial scouring as evidence by the thick sand diamicton, which was then eroded by a high-energy meltwater channel that deposited glaciofluvial sediment. The bedrock valley located in the area of Minton Lake is not interpreted to be connected with the bedrock valley associated with the NSZ fault in the area of the proposed open pit.

The hydraulic conductivity of the bedrock decreases with depth, with the upper portions being the most transmissive due to increased weathering and/or fracturing. The bedrock was subdivided into four hydrostratigraphic units based on transmissivity data collected from hydraulic testing conducted in the study area (Stantec 2017c). These units include the Shallow Bedrock, Upper Bedrock, Intermediate Bedrock, and Deep Bedrock Units. A comparison of the measured hydraulic conductivity in the bedrock for each of the hydrostratigraphic units is presented on Figure 3-1. The hydraulic conductivity was observed to be variable across each hydrostratigraphic unit, as described below.

3.3.5.1 Shallow Bedrock

The Shallow Bedrock unit consists of a zone of weathered and fractured bedrock that exists below the overburden deposits, or at ground surface where bedrock is exposed. The shallow bedrock is estimated to be approximately 10 m thick, with hydraulic conductivity estimates ranging from 5×10^{-8} to 5×10^{-4} m/s (Figure 3-1).

A mapped fault (NSZ Fault, Map 4) occurs in the area of the open pit. Hydraulic conductivity estimates are not available for the fault but are assumed to have the same properties as the host rock.

3.3.5.2 Upper Bedrock

The Upper Bedrock unit underlies the Shallow Bedrock and is estimated to be 40 m thick. The hydraulic conductivity for the Upper Bedrock is estimated to range from 1×10^{-8} to 2×10^{-7} m/s (Figure 3-1).

3.3.5.3 Intermediate Bedrock

The Intermediate Bedrock unit underlies the Upper Bedrock and is estimated to be 150 m thick. The hydraulic conductivity for the Intermediate Bedrock is estimated to range from 3×10^{-9} to 1×10^{-7} m/s (Figure 3-1).

3.3.5.4 Deep Bedrock

The Deep Bedrock unit is the deepest bedrock unit and is considered to be relatively impermeable, although discrete fractures may occur that increase the hydraulic conductivity locally. The hydraulic conductivity of this unit is estimated to range from 9×10^{-9} m/s (based on the hydraulic conductivity of bedrock with limited to no interconnected fractures) to 6×10^{-8} m/s (where fractures are present) (Figure 3-1).

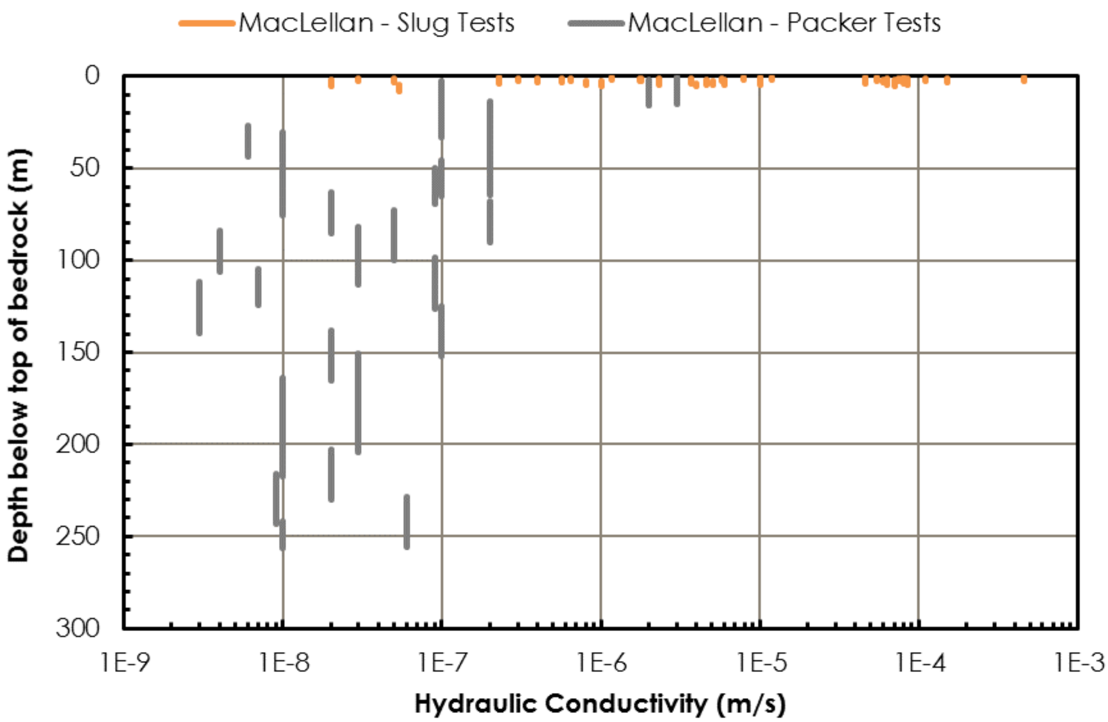

Figure 3-1 Hydraulic Conductivity Distribution in Bedrock with Depth

4.0 MODEL CONSTRUCTION AND CALIBRATION

This section describes the construction of the hydrogeology model using the hydrostratigraphic units of the conceptual model described in Section 3.0. The calibration of the model using available information on water levels and stream flow measurements collected as part of the baseline monitoring programs is also described.

The FEFLOW (version 7) groundwater modelling platform was chosen for this evaluation. It is a common platform for simulating and predicting groundwater flow in mining environments. In addition, it was selected as it is able to simulate heat transport and freeze-thaw processes (through a plug-in module) that affect the near-surface hydraulic conductivity. These processes were considered based on the discontinuous permafrost observed at the site.

An equivalent porous media (EPM) approach was selected to simulate the flow within the overburden and underlying bedrock. The EPM approach assumes that groundwater flow through fractured bedrock can be approximated by a porous medium with equivalent hydrogeologic properties of the bulk of the rock. The shallow weathered bedrock in the study area has the highest hydraulic conductivity reflecting the increased fracturing that is typical of shallow weathered bedrock in the Canadian Shield. The water level data collected within the shallow bedrock monitoring wells indicates a similar hydraulic response to the overburden system indicating a high degree of connectivity. Cook (2003) demonstrates regional connectivity occurs within the shallow bedrock zone and decreases with depth due to a decrease in fracture frequency and permeability. Groundwater flow in the bedrock is therefore expected to occur dominantly through this shallow bedrock unit.

As shown in Section 3.3.5, the permeability of the bedrock decreases with increasing depth, due to more discrete fracturing of the bedrock. At the regional scale, the EPM approach remains appropriate for predicting the effective groundwater discharge rates from the deeper bedrock into the open pit but reduces the reliability of predicted travel times through discrete fractures (Wels et al. 2012). Travel times through the discrete fractures using the EPM approach could be under-predicted (due to lower effective fracture porosities in the bedrock), or over-predicted, if there is poor connectivity of fractures at depth. This is appropriate based on the regional scale of the modelling and considering that flow was predicted to occur primarily through the shallow weathered bedrock, which is highly fractured, and therefore behaves like a porous medium.

4.1 MODEL DOMAIN

The extent of the model domain was chosen to correspond to the natural hydrogeologic boundaries and was to extend beyond the area where potential effects from the model predictions may impact on model boundaries. The model domain is presented on Map 10.

The model mesh is simulated to grade from coarser around the limits of the domain, to finer in the vicinity of the surface water features and the area of the proposed open pit. The mesh is composed of a total of 54,878 elements in each model layer with a total of 44 model layers.

The hydrostratigraphic units described in Section 3.0 were transferred to the FEFLOW model via the groundwater flow model output utility in Leapfrog Hydro®, with each hydrostratigraphic unit corresponding to a model layer presented in Table 4-1. Where hydrostratigraphic units were observed to be discontinuous across the study area and “pinch out”, the model layer was assigned a minimum thickness of 0.1 m and the hydraulic properties of the underlying hydrostratigraphic unit were assigned. The properties of the model layers are discussed further in Section 4.4.4.

Table 4-1 Relationship of Hydrostratigraphic Units and Model Layers

Hydrostratigraphic Unit	Model Layers	Thickness (m)
Overburden	1-5	Varies with hydrostratigraphic units
Shallow Bedrock	6-7	10
Upper Bedrock	8-14	40
Intermediate Bedrock	15-37	150
Deep Bedrock	38-44	Varies to bottom of model domain (elevation -15 m AMSL)

4.2 DISTRIBUTION OF HYDROGEOLOGIC PARAMETERS

The hydraulic conductivity, porosity, and recharge rate were assigned in the model based on the hydrostratigraphic units as defined in the conceptual model (Section 3.0). The geometric mean hydraulic conductivity values determined from the field-testing programs or characterized from grain size were used in the initial model set-up. The hydrostratigraphic units were assumed to be uniform and isotropic.

4.3 BOUNDARY CONDITIONS

4.3.1 Model Boundary

The model limits were assigned based on local watershed boundaries but were extended into neighbouring watersheds based on anticipated effects from the presence of the open pit. The model was extended to natural hydrologic/hydrogeologic boundaries, including watershed boundaries (assumed to be coincident with groundwater flow divides) or surface water features (also assumed to be coincident with groundwater flow divides). The model domain limits are presented on Map 10.

4.3.2 Recharge

The type of soil and vegetation present at surface is an important factor in determining whether precipitation will become runoff or groundwater recharge. A uniform recharge rate was applied across the domain, as the dominant surficial unit encountered at the MacLellan site was the glaciolacustrine unit. This is a contrast to the Gordon site where the surficial geology was more variable, and additional variability in the groundwater recharge was assigned. As shown in Section 4.4, the model was suitability calibrated to site conditions based on this single recharge value.

4.3.3 Lakes and Watercourses

As shown on Map 10 several lakes and watercourses are located within the model domain. Lakes and watercourses were assigned as boundary conditions in the model using a head-dependent flux boundary. This type of boundary condition determines the flow rate between the boundary condition and the aquifer based on the head assigned to the boundary condition. The vertical extent of the lakes was determined using available bathymetric data collected at the lakes (Stantec 2017b).

The interaction between the surface water in the lakes and watercourses and the groundwater in the underlying aquifers is defined by a “conductance” term. This term represents the presence of a layer of sediment on the lakebed or streambed that can affect the rate of water transferred between the lake or watercourse and the underlying model layer. A review of sediment analyses from lakes and watercourses showed that the sediments are generally fine-grained (Stantec 2017b) and the conductance term was assigned to the model based on an assumed hydraulic conductivity of 1×10^{-7} m/s.

4.4 CALIBRATION

4.4.1 Calibration Methodology

Model calibration was conducted using an iterative approach under steady-state conditions, followed by additional iterations to evaluate transient conditions. This involved a process where a flow simulation was carried out, the resulting groundwater levels, vertical hydraulic gradients, and baseflow rates to watercourses were compared to measured values, and the model input parameters were re-adjusted to achieve better agreement with observed (field measured) conditions and the overall interpreted groundwater flow directions. The process of model calibration involves the adjustment of model parameter values to match field-measured values within a pre-established range of error. A hybrid calibration approach was used that combined automated parameter estimation, facilitated using the Parameter Estimation code (PEST) (Doherty 2009), together with professional judgement and interpretation of the calibration results.

The calibration was completed using the following steps:

1. Prepare model files and input parameters
2. Run PEST to estimate parameter values that provide the best average fit to the observations
3. Review the model results
4. Adjust insensitive parameters from the PEST calibration (if any can be identified)
5. Repeat steps 2 through 4 until the model is determined to be adequately calibrated within acceptable ranges of error

Several parameters were adjusted during the calibration of the model, including:

- Hydraulic conductivity
- Specific yield
- Specific storage

These parameters were adjusted automatically using PEST over the ranges determined from field observations or literature values. A total of 22 parameters were adjusted during the calibration process. Key areas where manual adjustments in the automated calibration process were required included:

- Average annual recharge rate (steady-state)
- Monthly recharge rates (transient)
- Hydraulic conductivity of deep bedrock

4.4.2 Calibration to Water Levels

Model calibration was assessed by comparing model simulated water levels to observations collected from two water level datasets:

- Average annual water levels calculated from transient water levels
- Continuous water level data collected from onsite monitoring wells using pressure transducers and data recorders

The average annual water level targets at each location were calculated as the mean water level observed during the period of record available for each location and were used for the first calibration to steady-state conditions. Continuous water level observations from monitoring wells instrumented with pressure transducers were then used to attempt to fit transient water level targets based on transient recharge rates. The calculated average annual water level targets are presented in Table 4-2. The locations of the water level targets are shown on Map 11.

A plot of the simulated (modelled) versus observed (measured) average annual groundwater levels is shown in Figure 4-1. A line of perfect fit (e.g., a line having a slope of 1.0) is shown for comparison. Simulated groundwater levels that match the observed groundwater levels exactly will fall on this line. As shown on Figure 4-1 and in Table 4-2, there is generally good agreement with the water level targets; however, although there is a slight overprediction bias to the residuals. The largest residuals are observed at GBHM-06A, MWM-09A, MWM-09B and MWM-04.

Table 4-2 Water Level Calibration Residuals and Statistics

Location	Average Annual Target Water Level (m AMSL)	Simulated Average Annual Water Level (m AMSL)	Residual (m)	Target Type
MWM-01A	343.89	343.68	-0.21	Steady-state
MWM-02A	349.91	350.10	0.19	Steady-state

GBHM-10A	338.61	339.57	0.96	Steady-state
GBHM-10B	338.20	339.68	1.48	Steady-state
GBHM-12	335.64	340.14	4.50	Steady-state
GBHM-13A	343.21	343.61	0.40	Steady-state
GBHM-13B	343.21	343.50	0.29	Steady-state
Residual Statistics				
Sum of Squared Error (m²)			266	
Mean Error (m)			-0.62	
Absolute Mean Error (m)			1.35	
Root Mean Squared Error (m)			2.68	
Normalized Mean Squared Error (%)			8.0	

The statistical measures of the calibration to the water level data are reported in Table 4-2. These measures include the standard error of the estimate and the root mean squared (RMS) error. In evaluating the fit between the observed and the simulated water levels, the RMS error is usually regarded as the best measure (Anderson and Woessner 1991). The RMS error is essentially a standard deviation calculated as the average of the squared differences between the measured and the simulated water levels. If the ratio of the RMS error to the total water level differential over the model area is small (e.g., less than 10%; Spitz and Moreno 1996), then the errors are only a small part of the overall hydraulic response of the model. In this simulation, the ratio of the RMS error to the total water level differential (8.0%) is less than the recommended 10% threshold.

The fit of the model predicted transient water level trends to the water level hydrographs are provided in Figure 4-2. As shown, the model was unable to reproduce the seasonal recharge responses (i.e., an increase in water level in the spring recharge period following declines over the winter) in spite of efforts to vary the recharge on a monthly basis and adjusting the storage parameters (specific yield and specific storage) over the expected ranges during calibration. It is anticipated that the lack of these responses is due to the boundary conditions at the lakes and streams which were maintained at a constant stage throughout the year.

4.4.3 Calibration to Baseflow

The steady-state model calibration also included baseflow targets for a reach of the Keewatin River located between surface water monitoring locations AQM4 and AQM8 (Map 10). Streamflow data were developed from continuous water level data and flow measurements completed between 2015 and 2016 (Stantec 2017b). From the rating curves, the average annual streamflow rate for this reach of the Keewatin River is estimated to be approximately 0.20 cubic metres per second (m^3/s).

Baseflow to surface water features is provided primarily by groundwater discharge; however, where surface water features, such as lakes and wetlands, exist there is the potential to temporarily store precipitation and release water to a watercourse. This release of water from surface water storage can be difficult to distinguish from groundwater contributions to baseflow. Therefore, the baseflow targets are assumed to have contributions from groundwater discharge and delayed storage released from surface water features.

The steady-state model simulated groundwater discharge contributing to the Keewatin River reach discharge is 0.039 m^3/s, or approximately 20% of the average annual streamflow. This was considered to be a reasonable estimate of baseflow for this watershed, and therefore the calibration to baseflow is considered acceptable for this model.

4.4.4 Calibrated Model Parameters

The values of the hydrogeologic parameters that were determined from the calibration process are presented in Table 4-3. The hydraulic conductivity and storage coefficient values for the various hydrostratigraphic units generated by the model are within the ranges expected for the materials based on measured and literature values, as these were set as part of the calibration process.

The transient recharge rates determined at the end of the calibration are presented on Table 4-4.

Table 4-3 Calibrated Model Parameters

Parameter	Hydraulic Conductivity (m/s)	Specific Yield (-)	Specific Storage (1/m)	Average Annual Recharge (mm/yr)
Historical Mine Rock • Calibrated Value • Expected Range	• 1×10^{-3} • 1×10^{-3} to 1×10^{-2}	• 0.16 • 0.01 to 0.3	• 1.1×10^{-4} • 1×10^{-6} to 1×10^{-3}	• 120 • 4 to 146
Organics • Calibrated Value • Expected Range	• 1.2×10^{-5} • 1×10^{-8} to 1×10^{-5}	• 0.19 • 0.01 to 0.3	• 1.0×10^{-4} • 1×10^{-6} to 1×10^{-3}	
Diamicton • Calibrated Value • Expected Range	• 4.2×10^{-6} • 4×10^{-7} to 6×10^{-5}	• 0.20 • 0.01 to 0.3	• 1.0×10^{-4} • 1×10^{-6} to 1×10^{-3}	
Glaciolacustrine • Calibrated Value • Expected Range	• 8.3×10^{-6} • 1×10^{-7} to 6×10^{-5}	• 0.16 • 0.01 to 0.3	• 2.0×10^{-4} • 1×10^{-6} to 1×10^{-3}	
Shallow Bedrock • Calibrated Value • Expected Range	• 8.1×10^{-6} • 5×10^{-8} to 5×10^{-4}	• 0.06 • 0.01 to 0.3	• 1.0×10^{-4} • 4×10^{-5} to 2×10^{-3}	
Upper Bedrock • Calibrated Value • Expected Range	• 2.0×10^{-7} • 1×10^{-8} to 2×10^{-7}	n/a	• 1.0×10^{-4} • 4×10^{-5} to 2×10^{-3}	
Intermediate Bedrock • Calibrated Value • Expected Range	• 3.4×10^{-8} • 3×10^{-9} to 1×10^{-7}		• 1.0×10^{-4} • 4×10^{-5} to 2×10^{-3}	
Deep bedrock • Calibrated Value • Expected Range	• 1.3×10^{-8} • 9×10^{-9} to 6×10^{-8}		• 1.0×10^{-4} • 4×10^{-5} to 2×10^{-3}	

Table 4-4 Calibrated monthly recharge rates (mm/month)

Month	Recharge (mm/month)
January	0.4
February	0.4
March	0.7
April	13.5

December	1.7

5.0 MODEL APPLICATIONS

The calibrated groundwater flow model was used to quantify baseline groundwater levels and flow and groundwater discharge to the receiving environment under baseline conditions. The baseline model results were then used to compare to model predictions during construction, operation and closure phases of the Project. Section 5.1 presents the results from the baseline simulations using the calibrated model. Model modifications were then completed to allow simulation of the following phases:

- Construction (Mine Years -2 and 0) – initial dewatering of the underground workings and starter pit and groundwater discharge associated with the TMF
- Operation (Mine Years 1 to 3) – dewatering of open pit and groundwater discharge and seepage collection associated with the new MRSA and TMF
- Active reclamation/closure (after Mine Year 13)– filling of the open pit and groundwater discharge associated with the MRSA and TMF

Model results for the construction, operation, and closure phase of the Project are discussed in Sections 5.2 to 5.4, respectively.

5.1 BASELINE CONDITIONS

The calibrated groundwater flow model discussed in Section 4.0 was used to estimate the water table elevation (i.e., the top of the saturated water column) and groundwater flow under baseline conditions.

Map 12 shows the average annual water table elevation under baseline conditions from the calibrated groundwater flow model. The model provides a good representation of groundwater flow conditions in the area of the open pit and mimics the ground surface contours (Map 4), with groundwater flowing regionally to the south/southeast toward Cockeram Lake.

An estimate of groundwater discharge to the primary lakes and rivers/creeks located within the model domain was predicted using the model and is presented in Table 5-1. The location of the surface water features are presented in Map 10. The groundwater discharge rates were used to quantify changes to groundwater discharge during the construction, operation and closure phases, as presented in Sections 5.2 to 5.4.

In Table 5-1, a positive number indicates groundwater discharge to the surface water feature and a negative value indicates that the surface water feature is recharging the groundwater flow system. Baseflow values presented in the table represent the groundwater contributions to the features, and do not include contributions from surface water storage.

Table 5-1 Estimated Groundwater Discharge (m^3/s) to Watercourses and Lakes under Baseline Conditions

Watercourse	Groundwater to Surface Water	Surface Water to Groundwater	Net Groundwater to Surface Water[1]
Lakes			
Dot Lake	0.0470	0.0410	0.0060
Minton Lake	0.0390	0.0360	0.0030
Payne Lake	0.0034	0.0027	0.0007
Lake 2	0.0023	0.0012	0.0011
Lake 3	0.0035	0.0026	0.0009
Watercourses			
Keewatin River	0.0180	0.0090	0.0090
Lynn River	0.0055	0.0012	0.0043
Tributary of Keewatin River connecting with East Pond (Kee3-A1)	0.0001	0.0010	-0.0009
Tributary of Keewatin River (Kee3-B1)	0.0007	0.0007	0.0000
Watercourse from East Pond to Tributary of Keewatin River (Kee3-B2-A1)	0.0006	0.0016	-0.0010
Watercourse connecting Payne Lake and Keewatin River (Kee3-Pay1)	0.0001	0.0009	-0.0008

NOTES:

1 Positive value represents flow from groundwater to surface water
Negative value represents flow from surface water to groundwater

5.1.1 Historical Mine Rock Storage Area

A historical MRSA is located within the study area as shown on Map 3. Recharge through the historical MRSA has the potential to affect groundwater quality and as a result the model was used to determine the discharge location and flux of water recharging the groundwater flow system from beneath the MRSAs. The historical MRSA was incorporated into the model to understand the fate of recharge associated with this feature. To provide a conservative estimate of the groundwater discharge originating from the historical MRSA, groundwater flow simulations were conducted without the contact water collection system.

The calibrated groundwater flow model was used to better understand the fate of groundwater that originates from the historical MRSA and to estimate discharge rates to the receiving environment. A forward particle tracking approach was used, where a particle was released from each model node within the historical MRSA. The travel paths of the particles were simulated through the model domain until they arrived at a receptor, such as a lake or stream/creek. For this analysis, it was assumed that no subsurface seepage collection systems were in operation to provide a prediction of the maximum possible groundwater loading to the environment. This approach provides a conservative assessment of potential effects to the receiving environment.

The groundwater flux associated with each particle track was then determined and used to estimate the total discharge (Q) for the historical MRSA to the environment. This is illustrated on the conceptual cross-section shown in Figure 5-1 below. A particle trace is shown for a particle that originates in the historical MRSA and terminates at a lake. The groundwater discharge to the lake that is contributed by the cell in the historical MRSA is conservatively assumed to be equal to the total average annual recharge rate into that element (e.g., Qin = Qout) during the various phases of mine development. It was assumed that the groundwater recharge that enters the historical MRSA will be carried through to the receptors. As a result, the groundwater flow model may over-estimate groundwater discharge rates, as local seepage to intermittent surface water features or ditches that may be present in the area of the historical MRSA are not accounted for in the model.

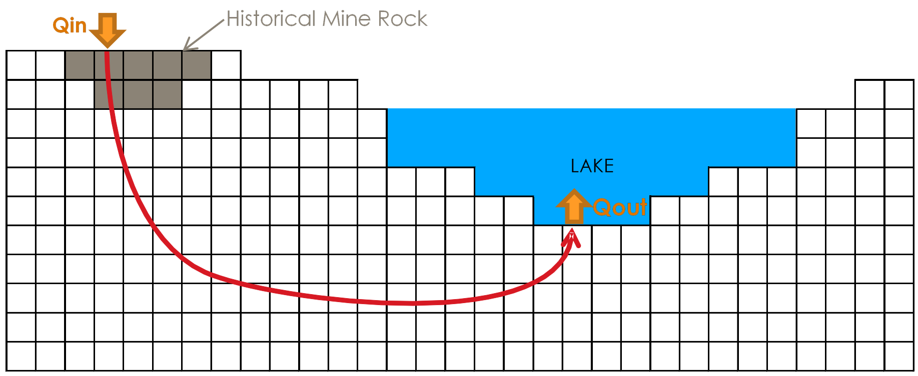

Figure 5-1 Conceptual Model Cross-Section Illustrating Particle Traces

The historical MRSA received an average recharge rate of 120 mm/yr under baseline conditions. The particle tracks from the historical MRSA under baseline conditions are presented on Map 13, and the estimated discharge rates and travel time statistics to the receiving environment are presented on Table 5-2. As shown on Map 13 and Table 5-2, all of the particles originating from the historical MRSA discharge to the Keewatin River, at a rate of 1.1×10^{-5} m^3/s. However, these flow paths are very long as they flow into the bedrock unit, and the estimated travel time from the water table to the Keewatin River are estimated to exceed 2,000,000 years. This is based on the relatively deep flow path these particles take through the bedrock before arriving at the Keewatin River.

Table 5-2 Predicted Groundwater Discharge Rates (m^3/s) from Historical Mine Rock Storage Area to Receiving Environment at Baseline

Mine Rock Storage Area	Receptor	Discharge (m^3/s)	Travel Time (years)		
			Minimum	Mean	Maximum
Historical Mine Rock	Keewatin River	1.1×10^{-5}	2,085,000	2,477,000	3,452,000

5.2 CONSTRUCTION

Construction activities at the MacLellan site are anticipated to begin Mine Year -2 with the construction of the initial phases of the TMF and new MRSA, and the construction of the starter pit. These activities are anticipated to potentially influence groundwater levels and flow through the initial dewatering of the starter pit and underground workings, and the change in recharge at the base of the new MRSA and TMF. The historical MRSA will be removed during the construction of the starter pit. While these activities will continue into the initial operating years, they have been simulated separately in the construction phase to document the potential changes to groundwater levels and flow in the early phases of Project development.

5.2.1 Model Setup

Starting with the calibrated groundwater flow model, the following modifications were completed to represent the dewatering of the starter pit and the fate of groundwater originating from the MRSA and TMF. The modifications are discussed below for each Project component.

5.2.1.1 Dewatering Starter Pit

The construction and operation of the open pit has the potential to change the baseline groundwater flow conditions, particularly through the lowering of the water table in the vicinity of the open pit. This will be accomplished through the collection of sump water at the base of the starter pit, and through the dewatering of the underground workings. The dewatering of the underground workings was expected to be staged based on the development of the open pit and will be progressively lowered with the base of the open pit. The lowering of the water table associated with the dewatering of the open pit and underground workings may also affect groundwater discharge to surface water features near the open pit and the discharge associated with the MRSA or TMF.

To evaluate the effects of groundwater inflows to the starter pit/underground workings during the construction phase, the calibrated groundwater flow model was modified to represent the extent and depth of the pit as seepage faces. The conductance of the seepage face nodes was specified based on the hydraulic conductivity in the elements surrounding the nodes.

The hydraulic conductivity of the seepage face nodes was adjusted on a monthly basis to reflect the reduced hydraulic conductivity based on freezing and thawing of the seepage face. The hydraulic conductivity was determined using the heat and transport functionality of FEFLOW with the Freeze-Thaw Model (FTM) plugin. Simulations of the freezing and thawing were used to determine the changes in hydraulic conductivity predicted based on the average monthly air temperatures. Due to the additional computational burden of running the model in heat and transport mode, the simulation of effects of freezing on dewatering were conducted with only the flow components in FEFLOW. These effects were incorporated into the groundwater flow model by specifying the variable hydraulic conductivity at the pit face due to freezing as determined using the FTM plugin.

5.2.1.2 Mine Rock Storage Area

The Project includes a new MRSA for the collection of surplus mine rock at the MacLellan site (Map 3). Recharge through the MRSA has the potential to affect groundwater quality and as a result the model was used to determine the discharge location and flux of water recharging the groundwater flow system from beneath the MRSA. Because of the short duration of construction compared to the travel time of groundwater discharge originating from the MRSA, groundwater flow simulations were conducted without the contact water collection systems for the construction phase.

The structure of the MRSA was added to the groundwater flow model as a layer of high permeability material on top of the existing ground surface. The groundwater recharge within the footprint of the MRSA was estimated with a water balance approach as presented in Water Balance and Water Quality Model Technical Modelling Report: MacLellan Site (Stantec 2020d).

The infiltration rate into the MRSA considers losses due to evaporation, surface runoff, and micropore and macropore flow within the MRSA. The infiltration rate during construction is predicted to be approximately 25% of the total precipitation. As the MRSA is developed, it will take time before the MRSA reaches saturation and the precipitation infiltrating into the pile will equal the volume of water leaving the base of the pile (e.g., steady-state conditions). Infiltration that reaches the base of these piles is expected to either flow laterally along the ground surface and report as seepage at the toe of the pile (toe seepage) or recharge the underlying groundwater flow system based on the permeability of the underlying soils.

To determine the proportion of infiltration that recharges the groundwater flow system beneath the MRSA, a SEEP/W model was used in conjunction with the groundwater flow model. The SEEP/W model was used to determine the amount of seepage that is collected in toe seepage drains (i.e., lateral seepage from surface runoff or from the waste rock/native overburden interface). The lateral drainage from within the waste rock pile was not allowed to exceed the calibrated recharge rates in the groundwater flow model. The average recharge rate to the groundwater flow system under the MRSA was 120 mm/yr.

The groundwater flow model was used to predict the discharge location, flux of water recharging the groundwater flow system from beneath the MRSA, and associated groundwater flow paths, using the method described for the historical MRSA in Section 5.1.1.

5.2.1.3 Tailings Management Facility

The TMF is located within the north eastern portion of the study area as shown on Map 3. Recharge through the TMF has the potential to affect groundwater quality and as a result the model was used to determine the discharge location and flux of water recharging the groundwater flow system from beneath the TMF.

The materials for the TMF were simulated using material placed in a single layer in the groundwater flow model, placed on top of the existing ground surface. The dams of the TMF were constructed of coarse rock of high permeability, with a layer of HDPE placed on the upstream side of the dam, between the tailings and the rock fill of the dam. During construction, the tailings were assumed to have an initial hydraulic conductivity of 1×10^{-6} m/s based on the consolidation testing performed on the tailings (Golder 2016). The HDPE liner on the upstream side of the rock fill is assumed to have a hydraulic conductivity of 1×10^{-9} m/s, and the rock fill of the dam a hydraulic conductivity of 1×10^{-3} m/s.

Recharge through the first phase of the TMF during construction was assumed to be controlled by the presence of a pond in the TMF at elevation 359.4 m AMSL. This pond elevation was assigned as a constant head boundary over the entire footprint of the TMF and is assumed to be controlled by the deposition of water from the tailings slurry and the reclaim of water back to the mill. Because of the short duration of construction compared to the travel time of groundwater discharge originating from the TMF, groundwater flow simulations were conducted without the contact water collection systems for the construction phase

5.2.2 Results

5.2.2.1 Starter Pit Dewatering

The predicted total groundwater inflow rates to the starter pit during construction are presented on Figure 5-2. The groundwater inflow rates are predicted to be initially high (0.0123 m^3/s for the first month), with decreasing flows during the winter months, followed by peak flows associated with the spring freshet. The average annual groundwater inflow rate to the pits is predicted to be 0.0063 m^3/s at the end of the construction period.

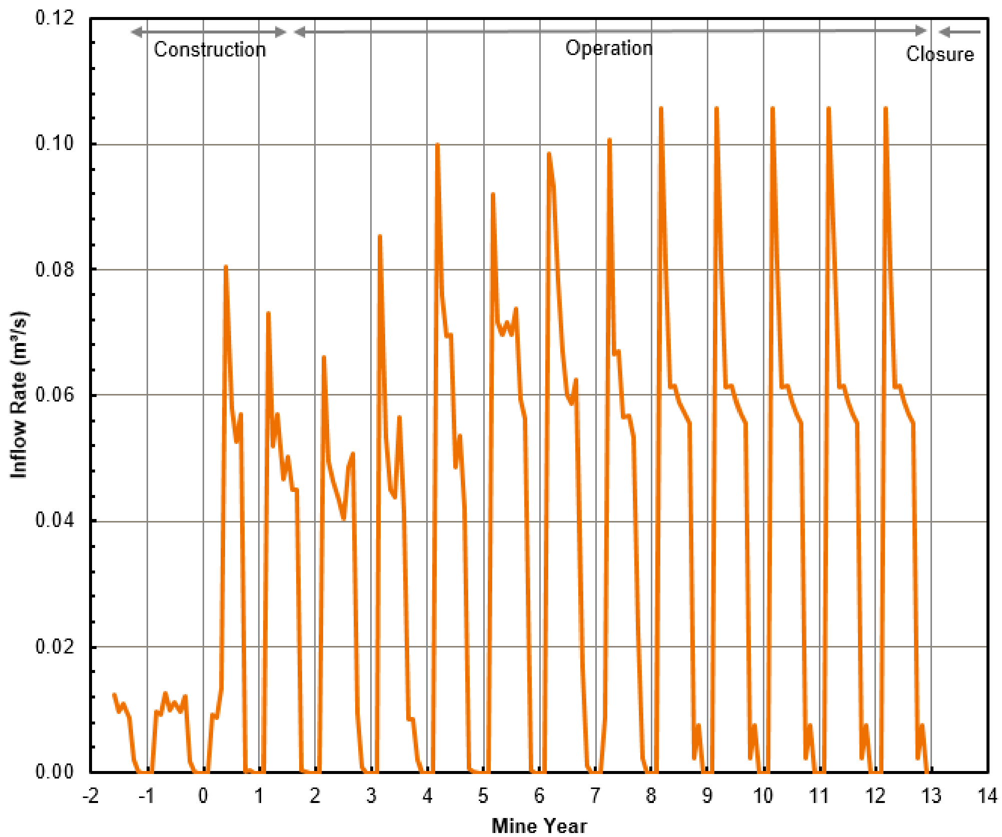

Figure 5-2 Calculated groundwater inflows to Open Pit over Life of Mine - Construction and operation

The predicted groundwater elevation contours and drawdown contours at the end of construction period are presented on Map 14 and Map 15, respectively. In the area of the starter pit, groundwater levels are lowered by approximately 1.0 m or less within 200 m of the pit. The drawdown extends predominantly south of the pit due to the constraints of Keewatin River. The construction of the TMF is predicted to increase the water level more than 1 m above baseline water levels for about 750 to 1,000 m downgradient of the TMF, as shown on Map 15.

Table 5-3 presents the comparison of baseline groundwater discharge rates with effects of the TMF and starter pit dewatering at the end of the construction period. As shown in Table 5-3, there is a negligible change in the groundwater discharge to surface water receivers (i.e. less than 0.003 m^3/s) at the end of construction except for the Lynn River and Keewatin River. The Lynn River, in the vicinity of the open pit, is predicted to shift from gaining groundwater to losing groundwater. The Lynn River is a boundary condition on the limits of the groundwater flow model, and the change in groundwater discharge to the Lynn River is likely a model artifact since the changes in groundwater table (Map 15) due to open pit dewatering does not extend to the Lynn River and the predicted change during construction does not extend to operations. The largest change in groundwater discharge is predicted at the Keewatin River, which is predicted to contribute 0.015 m^3/s of flow during construction compared to the 0.009 m^3/s predicted during baseline conditions. This increase in groundwater discharge to the Keewatin River is due to the increased hydraulic gradient to the river due to mounding associated with the TMF and limited dewatering of the starter pit.

Table 5-3 Estimated Groundwater Discharge (m^3/s) to Watercourses and Lakes at End of Construction

Watercourse	Baseline[1]	End of Construction[1]	Change from Baseline[1]
Lakes			
Dot Lake	0.0060	0.0060	0.0000
Minton Lake	0.0030	0.0040	0.0010
Payne Lake	0.0007	0.0014	0.0007
Lake 2	0.0011	0.0011	0.0000
Lake 3	0.0009	0.0009	0.0000
Watercourses			
Keewatin River	0.0090	0.0150	0.0060
Lynn River	0.0043	-0.0007	-0.0050
Tributary of Keewatin River connecting with East Pond (Kee3-A1)	-0.0009	-0.0009	0.0000
Tributary of Keewatin River (Kee3-B1)	<0.0001	<0.0001	0.0000
Watercourse from East Pond to Tributary of Keewatin River (Kee3-B2-A1)	-0.0010	-0.0010	0.0000
Watercourse connecting Payne Lake and Keewatin River (Kee3-Pay1)	-0.0008	-0.0007	0.0001

NOTES:
1. Positive value represents flow from groundwater to surface water
   Negative value represents flow from surface water to groundwater

5.2.2.2 Mine Rock Storage Area and Tailings Management Facility

The fate of groundwater that recharges beneath the TMF was determined by conducting particle tracking. The particle traces at the end of construction are presented on Map 16 and are summarized on Table 5-4 by their predicted ultimate receptor, assuming no contact water collection system operating. This assumption provides a conservative assessment of potential groundwater discharge to the receiving environment during the relatively short construction period. The inclusion of the contact water collection system would decrease the groundwater discharge from these areas.

Table 5-4 Predicted Groundwater Discharge Rates (m^3/s) from Tailings Management Facility to Receiving Environment during Construction

Project Infrastructure	Receptor	Discharge (arriving within 2 years) (m^3/s)	Travel Time (years)		
			Minimum	Mean	Maximum
TMF	Watercourse connecting Payne Lake and Keewatin River (Kee3-Pay1)	0.000003	1	5	15
	Dot Lake	n/a[1]	18	25	32
	Keewatin River	n/a[1]	2	7	32
	Tributary of Keewatin River (Kee3-B1)	n/a[1]	4	18	124
	Minton Lake	n/a[1]	2	16	108
	Cockeram Lake	n/a[1]	42	65	91

Notes:

1: not applicable, travel time from source to receptor is greater than the time period for construction, therefore no discharge from source to receptor is anticipated during construction.

As shown on Table 5-4, none of the particles that originate in the TMF are predicted to arrive at receptors except Payne Lake Tributary (Kee3-Pay1) during the two-year construction period, with the majority of the particles from the TMF predicted to arrive after the construction period. The MRSA will not become saturated during the construction period and therefore, no seepage out the base of the MRSA is predicted during construction. As the particle traces are used to quantify the inflow rates to the open pit and discharge to surface water features from the MRSA and the TMF, but no particles except to Payne Lake arrived within the construction period, the predicted groundwater flow to the receptors originating from these areas during the construction period are estimated to be zero.

5.3 OPERATION

The groundwater model was subsequently modified from the construction phase to simulate the effects of the Project during operation on groundwater levels and flow and the fate of groundwater originating from the MRSA and TMF during operation. As part of these simulations the model was used to predict groundwater inflows to the open pit and to evaluate the flow paths and groundwater discharge rates to receptors for recharge that originates from the MRSA and TMF.

5.3.1 Model Setup

Starting with the calibrated groundwater flow model and modifications completed for construction, the following additional modifications were completed:

- development and dewatering of the open pit

- variations in recharge rates related to the development of the MRSA and TMF
- the installation of dewatering ditches around the perimeter of the MRSA and TMF to mitigate the migration of solutes from these areas

The modifications are discussed below for each Project component.

5.3.1.1 Open Pit Dewatering

To evaluate the effects of groundwater inflows to the open pit the calibrated groundwater flow model was modified to include the extents and depths of the open pit for two specified stages of development of the open pit as discussed below:

- Mine Year 5: representing the intermediate development stage of the open pit.
- Mine Year 13: representing the ultimate extent of the open pit development at the completion of mining at the MacLellan site.

Model nodes that were intersected by the walls or floor of the open pit were identified and assigned as a seepage face boundary condition in the model. Model nodes that were located above the seepage face nodes within the footprint of the open pit were set as inactive.

The hydraulic conductivity of the seepage face nodes was adjusted on a monthly basis to reflect the reduced hydraulic conductivity based on freezing and thawing of the seepage face. The hydraulic conductivity was determined using the heat and transport functionality of FEFLOW with the FTM plugin. Simulations of the freezing and thawing were used to determine the changes in hydraulic conductivity predicted based on the average monthly air temperatures. Due to the additional computational burden of running the model in heat and transport mode, the simulation of effects of freezing on dewatering were conducted with only the flow components in FEFLOW, using the variable hydraulic conductivity at the pit face due to freezing as inputs that was determined using the FTM plugin.

Each of the open pit development stages (i.e., Mine Year -2 (construction), Mine Year 5, and Mine Year 13) were simulated in the model as separate transient model runs, with the results of the previous runs used as the starting condition of the next run. Year -2 model run presented in Section 5.2 represents the dewatering of the starter pit. An intermediate pit stage of the mine development (Mine Year 5) was used as the next condition, and the ultimate pit stage at the end of mine life (Mine Year 13) used as the final condition.

5.3.1.2 Mine Rock Storage Area and Tailings Management Facility

The Project includes a new MRSA and TMF during operation, which were represented in a similar manner to that described in Sections 5.2.1.2 and 5.2.1.3, with the MRSA and TMF constructed to their full extent at the end of the simulated stages of mine development.

Alterations to how the TMF was represented in the model at end of mine life included the reduction of the bulk hydraulic conductivity from 1×10^{-6} m/s to 1×10^{-7} m/s, to reflect the consolidation of tailings at the base of the pile. In addition, the constant head boundary representing the tailings pond was removed, and the total recharge into the TMF was adjusted to maintain a tailings ponds at the top of the tailings surface at the end of operations.

5.3.1.3 Seepage Collection System

A seepage collection system is proposed to be installed around the perimeter of the TMF and MRSA, as shown on Map 3. The seepage collection system was simulated in the model using a seepage face boundary condition, based on a series of 2 m deep ditches. This depth was selected as it was determined to be the most effective at intercepting a portion of the groundwater seepage from the TMF and MRSA, as the water table is below this depth in several locations in this upland area.

5.3.2 Results

5.3.2.1 Open Pit Dewatering

The predicted pumping rates to maintain a dewatered seepage face for the three model runs were used to interpret groundwater pumping rates over the life of mine (LOM) and are presented in Figure 5-2. These pumping rates only consider inflows to the open pit due to groundwater and do not consider surface water runoff or precipitation inflows that may enter the open pit. As dewatering progresses the average annual groundwater inflow rate increases from 0.006 m^3/s at the end of the construction period to 0.041 m^3/s at end of operation.

The simulated water table at the end of mine life is presented in Map 17 and Map 18, with and without the effect of the seepage collection ditches, respectively. Changes in the water table elevation due to dewatering of the open pit are evident primarily in the area south of the open pit. The drawdown or change in water table elevation due to dewatering of the open pit, at end of LOM in comparison to baseline conditions is shown on Map 19 and Map 20, with and without the effect of the seepage collection ditches, respectively. Dewatering of the open pit will lower the water table by up to 1.0 m that extends over an area of approximately 800 m south of the open pit, increasing to more than 10 m within 600 m of the open pit. The induced infiltration of surface water to the shallow overburden and bedrock limits the extent of the drawdowns. East Pond is anticipated to be dewatered during operations due to the lowering of the water table by up to 5 m and the loss of catchment due to open pit development. Map 19 and Map 20 also presents the predicted zone of influence of the TMF on groundwater levels compared to baseline conditions. As identified by the -0.5 m drawdown contour, mounding of the water table within the area of the TMF is predicted to extend up to 1,000 m from the limits of the TMF. Drawdown due to the operation of the seepage collection ditches around the perimeter of the TMF and MRSA are predicted to lower the water table up to 1 m in the immediate vicinity of the collection ditches, particularly along the eastern and southern portions of the MRSA and will limit the extent of mounding of the water table from development of the TMF.

Table 5-5 presents the comparison of groundwater discharge rates with effects of the dewatering at the end of the operation period (i.e., end of mining). Watercourse Kee3-Pay1 in the vicinity of the open pit is predicted to shift from losing groundwater in baseline to gaining groundwater in operations due to mounding of the water table in the vicinity of the TMF and an increased hydraulic gradient to Kee3-Pay1. The rate of groundwater discharge to Payne Lake, Minton Lake, Lake 2, and Lake 3 increases from baseline conditions to the end of operation due to further development of the TMF and 50% saturation of the MRSA which results in further mounding of water table in the vicinity of the TMF compared to construction. The mounding of the water table increases the horizontal hydraulic gradient toward these lakes. The rate of groundwater recharge from watercourse Kee3-B2-A1 increases at the end of operation compared to baseline conditions due to dewatering of the open pit. For the remaining watercourses and lakes, the changes to the groundwater discharge rates are relatively small (less than 0.003 m^3/s) compared to the baseline conditions and the overall anticipated flow rates in the surface water features.

Table 5-5 Estimated Groundwater Discharge to Watercourses and Lakes at End of Operations (m^3/s) without Seepage Collection Ditches

Watercourse	Baseline[1]	End of Operation[1]	Change from Baseline
Lakes			
Dot Lake	0.0060	0.0070	0.0010
Minton Lake	0.0030	0.0060	0.0030
Payne Lake	0.0007	0.0035	0.0028
Lake 2	0.0011	0.0019	0.0008
Lake 3	0.0009	0.0023	0.0014
Watercourses			
Keewatin River	0.0090	0.0083	-0.0007
Lynn River	0.0043	0.0057	0.0014
Tributary of Keewatin River connecting with East Pond (Kee3-A1)	-0.0009	-0.0003	0.0006
Tributary of Keewatin River (Kee3-B1)	<0.0001	0.0018	0.0018
Watercourse from East Pond to Tributary of Keewatin River (Kee3-B2-A1)	-0.0010	-0.0041	-0.0032
Watercourse connecting Payne Lake and Keewatin River (Kee3-Pay1)	-0.0008	0.0027	0.0035

NOTES:
1. Positive value represents flow from groundwater to surface water
   Negative value represents flow from surface water to groundwater

The operation of seepage collection ditches around the perimeter of the TMF and MRSA were also simulated in the model. The effects of these features on the groundwater discharge is presented on Table 5-6. The operation of collection ditches is predicted to collect 0.0098 m^3/s of groundwater and will have relatively minor changes to lake baseflows compared to operation without ditches.

Table 5-6 Estimated Groundwater Discharge to Watercourses and Lakes at End of Operations (m^3/s) with 2-metre Deep Seepage Collection Ditches

Watercourse	Baseline[1]	End of Operation[1]	Change from Baseline
Lakes			
Dot Lake	0.0060	0.0060	0.0000

Watercourse connecting Payne Lake and Keewatin River (Kee3-Pay1)	-0.0008	0.0022	0.0030
Seepage Collection Ditches	0	0.0098	0.0098

NOTES:
1. Positive value represents discharge of groundwater to the receiver
   Negative value represents surface water infiltration or recharge from receiver to the groundwater flow system

5.3.2.2 Sensitivity of Open Pit Dewatering to Bedrock Hydraulic Conductivity

The calibration of the groundwater model was based on the fit of water levels by adjusting the assumed uniform hydraulic conductivity of hydrostratigraphic units. It is noted from Table 4-3 that the hydraulic conductivity range for the shallow bedrock has the highest observed range of the hydrostratigraphic units, and that the hydraulic conductivity of the shallow bedrock is highest of the bedrock units (Figure 3-1). As the groundwater flow within the study area is expected to occur dominantly through the shallow bedrock, a sensitivity analysis was conducted to assess the effects of adjusting the hydraulic conductivity within the shallow bedrock on the expected inflows to the open pit.

The sensitivity analysis consisted of two scenarios where the hydraulic conductivity of the shallow bedrock layers was adjusted. The details of the analysis are presented in Table 5-7. The results are compared against the average annual end of mine (EOM) inflow rates to the open pit as presented above, Section 5.3.2.1, as a base case.

Table 5-7 Sensitivity Analysis of Groundwater Inflows to Bedrock Hydraulic Conductivity – Mine Year 13

Scenario	Hydraulic Conductivity of Shallow Bedrock (m/s)	Total Pit Inflow (m^3/s)	Change from Baseline	Contribution from Keewatin River (m^3/s)
Base Case	8.1×10^{-6}	0.041	0	0.0071
1	8.1×10^{-7}	0.029	29%	0.0043
2	8.1×10^{-5}	0.125	206%	0.023

As shown on Table 5-7, the total inflow to the open pit is very sensitive to the value of hydraulic conductivity assigned to the shallow bedrock, particularly as the hydraulic conductivity increases. The inflow rates vary by less than 30% with an order of magnitude decrease in hydraulic conductivity but increases by about 200% with an order of magnitude increase in hydraulic conductivity. It is noted that increasing the hydraulic conductivity of the shallow bedrock an order of magnitude would also have a detrimental effect on the calibration of the model. Therefore, the hydraulic conductivity values determined during the calibration of the model are considered representative and are carried forward in the analyses.

5.3.2.3 Mine Rock Storage Area and Tailings Management Facility

The fate of groundwater that recharges beneath the MRSA and TMF was determined through particle tracking. The particle traces at the EOM are presented on Map 21 assuming no contact water collection system operating. This assumption provides a conservative assessment of potential groundwater discharge to the receiving environment. The inclusion of the contact water collection system would decrease the groundwater discharge from these areas. The particle traces were used to quantify the inflow rates and travel times to the open pit and discharge to surface water features from the MRSA and TMF and are presented in Table 5-8.

Table 5-8 Predicted Groundwater Discharge Rates (m^3/s) from Mine Rock Storage Area and Tailings Management Facility to Receiving Environment at End of Operation without Seepage Collection Ditches

Project Infrastructure	Receptor	Discharge (m^3/s)	Travel Time (years)			Discharge Arriving within 300 years (m^3/s)
			Minimum	Mean	Maximum	
MRSA	Keewatin River	0.000065	94	310	3,189	0.000052
	Tributary of Keewatin River (Kee3-B1)	0.001300	3	81	1,853	0.001189
	Open Pit	0.001300	18	603	46,397	0.000969
	Minton Lake	0.004500	20	754	8,376	0.003063
	Cockeram Lake	0.000008	131,865	132,155	132,445	0.000000
TMF	Watercourse connecting Payne Lake and Keewatin River (Kee3-Pay1)	0.000120	140	210	326	0.000121
	Keewatin River	0.000225	103	1,302	32,869	0.000131
	Tributary of Keewatin River (Kee3-B1)	0.003000	1	327	5,268	0.001013
	Open Pit	0.000300	178	11,364	48,415	0.000000
	Minton Lake	0.001100	3	4,447	29,497	0.000039
	Cockeram Lake	0.000082	108,755	196,541	368,155	0.000000
	Subsurface Seepage to Fen	0.000073	1	129	1,226	0.000067

As shown on Table 5-8, the groundwater recharge from beneath the TMF without ditches discharges primarily to a tributary to Keewatin River Tributary (61%) or Minton Lake (22%) with smaller contributions to Payne Lake Tributary (2%), Keewatin River (5%), the open pit (6%), or Cockeram Lake (2%). The mean advective travel times vary from 210 years to the Payne Lake Tributary, to more than 196,000 years to Cockeram Lake. Groundwater recharge from beneath the MRSA discharges without ditches primarily to Minton Lake (62%), Keewatin River Tributary (18%), or the open pit (18%) with the remainder discharging to the Keewatin River (1%) or Cockeram Lake (<1%). The mean advective travel times vary from 81 years to Keewatin River Tributary to in excess of 132,000 years to Cockeram Lake.

Similarly, the fate of groundwater that recharges beneath the MRSA and TMF with a 2-m perimeter seepage collection ditch was also determined by conducting particle tracking. The particle traces at the end of operation with the 2-m perimeter ditch are presented on Map 22. The particle traces were used to quantify the inflow rates and travel times to the open pit and discharge to surface water features from each MRSA and are presented in Table 5-9.

Table 5-9 Predicted Groundwater Discharge Rates (m^3/s) from Mine Rock Storage Area and Tailings Management Facility to Receiving Environment at End of Operation with 2-metre Deep Seepage Collection Ditches

Project Infrastructure	Receptor	Discharge (m^3/s)	Travel Time (years)			Discharge arriving within 300 years (m^3/s)
			Minimum	Mean	Maximum	
MRSA	Keewatin River	0.000031	87	117	337	0.000030
	Tributary of Keewatin River (Kee3-B1)	0.001500	1	20	364	0.001412
	Open Pit	0.000500	14	168	14,333	0.000513
	Minton Lake	0.001500	3	70	264	0.001499
	Seepage Collection Ditches	0.003600	0	43	595	0.003431
TMF	Watercourse connecting Payne Lake and Keewatin River (Kee3-Pay1)	0.000004	134	1,533	4,456	0.000001
	Keewatin River	0.000116	90	229	3,200	0.000112
	Tributary of Keewatin River (Kee3-B1)	0.002500	2	248	4,501	0.002010
	Open Pit	0.000300	807	5,071	30,801	0.000000
	Minton Lake	0.001500	5	437	12,077	0.000486
	Cockeram Lake	0.000128	32,796	130,146	550,064	0.000000
	Seepage Collection Ditches	0.000352	1	196	807	0.000217

As shown on Table 5-9, the seepage collection ditches are predicted to capture 7% and 50% of the overall seepage from the TMF and MRSA. The groundwater recharge from beneath the TMF with ditches discharges primarily to a tributary to Keewatin River tributary (51%) or Minton Lake (31%) with smaller contributions to Payne Lake Tributary (<1%), Keewatin River (2%), the open pit (6%), or Cockeram Lake (2%). The mean advective travel times vary from 229 years to the Keewatin River, to more than 130,000 years to Cockeram Lake. Groundwater recharge from beneath the MRSA with ditches discharges primarily to Minton Lake (21%) or Keewatin River Tributary (21%), with the remainder discharging to the open pit (7%), or Keewatin River (<1%). The mean advective travel times vary from 20 years to Keewatin River Tributary to in excess of 168 to the open pit.

Given the long flow paths for seepage from the MRSA and TMF, the proportion of seepage arriving at a receiver within 300 years is provided for reference in Table 5-8 and Table 5-9. Three hundred years travel time was used as a threshold for input to the water balance model (Stantec 2020d), which had a 300-year run time.

5.4 CLOSURE

The groundwater model was subsequently modified from the operation phase to simulate the effects of the Project during closure on groundwater levels and flow and the fate of groundwater originating from the MRSA and TMF. As part of these simulations the model was used to predict groundwater inflows to the open pit as it was filling, and to evaluate the flow paths and groundwater discharge rates to receptors for recharge that originates from the MRSA and TMF.

5.4.1 Model Setup

Starting with the calibrated groundwater flow model and modifications completed for operation, the pit boundary was modified to allow for the pit to fill over time due to groundwater. The modifications to the operation model are discussed below for each Project component.

5.4.1.1 Open Pit Filling

The groundwater inflows to the open pit as it is filled during closure was simulated in the groundwater flow model by modifying the seepage face boundary conditions at the ultimate extent of the open pit development at the completion of mining at the MacLellan site. The pit inflow rate was estimated by removing the seepage face boundary conditions and monitoring the predicted water level in the pit lake and the inflow rate to the pit lake.

5.4.1.2 Mine Rock Storage Area and Tailings Management Facility

The new MRSA and TMF as represented during operation with the MRSA and TMF constructed to their full extent at the stages of mine development were maintained throughout closure. Although progressive rehabilitation of the MRSA is proposed by application of a cover, the cover is not anticipated to reduce the groundwater recharge rate out the base of the MRSA. Simulations of the continued operation of the perimeter seepage collection ditches were conducted, as well as the removal of the seepage collection ditches post-closure (i.e., once the water quality is suitable for direct discharge to the receiving environment).

5.4.2 Results

5.4.2.1 Open Pit Filling

The rate of groundwater inflow and time for the open pit to fill after the end of mining activities is presented in Figure 5-10. The groundwater inflow rate decreases from 0.037 m^3/s at a pit lake elevation of 0 m AMSL to 0.005 m^3/s at a final pit lake level of 330 m AMSL. The groundwater inflow rates to the open pit presented on Figure 5-10 were incorporated into the water balance (Stantec 2020d) to evaluate the overall time to fill the open pit during closure considering both groundwater and surface water sources.

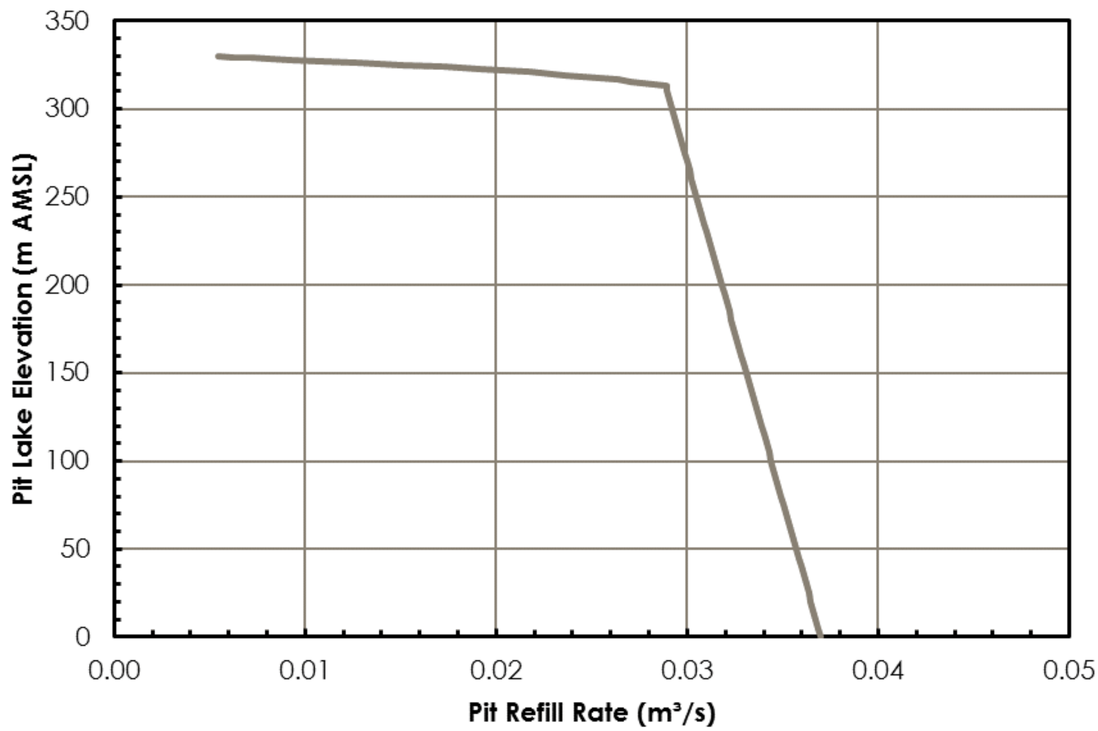

Figure 5-3 Pit Filling Rates During Closure

The water table elevations at the end of closure are presented on Map 23 and Map 24, not including and including the effect of the seepage collection ditches, and the change of the water table position compared to baseline conditions are presented on Map 25 and Map 26, respectively. As shown, at the end of closure with the seepage collection ditches, the water table is predicted to return to near baseline conditions within the vicinity of the open pit. The mounding of the water table is limited by the seepage collection ditches around the perimeter of the TMF and MRSA (Map 26). Mounding of the water table is confined to the footprint of the TMF and MRSA as well as the fen located east of the MRSA. Drawdown due to the presence of the seepage collection ditches around the perimeter of the TMF and MRSA is predicted in the direct vicinity of the collection ditches, specifically located along the eastern and southern portions of the MRSA. Map 25 presents the simulated drawdown in comparison to baseline conditions with the decommissioning of the seepage collection ditches around the MRSA and TMF for comparison. Without the seepage collection ditches, the mounding of the water table extends up to 2,400 m from the limits of the TMF. As the groundwater level returns to near baseline conditions, it is anticipated that at least a portion of East Pond may refill.

Table 5-10 presents the comparison of baseline groundwater discharge rates with effects of the pit lake on the surface water flows at closure (i.e., after the pit lake is full) without seepage collection ditches around the TMF and MRSA. The groundwater flows to the receptors are predicted to return to near baseline levels once the pit is full. The predicted changes to the groundwater flow rates are relatively small (generally less than 0.003 m^3/s) compared to the overall anticipated flow rates in the surface water features and are not anticipated to affect water levels in the streams or lakes. The largest change in baseline to closure groundwater discharge rates is predicted at the tributary to Keewatin River (Kee3-B2-A1), which is predicted to lose 0.0032 m^3/s more flow in closure than during baseline conditions, which is consistent with the effects observed during operations.

Table 5-10 Estimated Groundwater Discharge to Watercourses and Lakes at End of Closure (m^3/s) without Seepage Collection Ditches

Watercourse	Baseline[1]	Post-Closure[1]	Change from Baseline
Lakes			
Dot Lake	0.0060	0.0060	<<0.0001

NOTES:
1 Positive value represents flow from groundwater to surface water
Negative value represents flow from surface water to groundwater

The operation of seepage collection ditches around the perimeter of the TMF and MRSA were also simulated in the model. The effects of these features on the groundwater discharge is presented on Table 5-11. The operation of collection ditches is predicted to collect 0.0104 m^3/s of groundwater and will have relatively minor changes to lake baseflows compared to operation without ditches.

5.4.2.2 Mine Rock Storage Area and Tailings Management Facility

The fate of groundwater that recharges beneath the MRSA and TMF was determined by conducting particle tracking. The particle traces at closure are presented on Map 27 assuming no contact water collection system operating. This assumption provides a conservative assessment of potential groundwater discharge to the receiving environment. The inclusion of the contact water collection system would decrease the groundwater discharge from the MRSA and TMF. The particle traces were used to quantify the inflow rates and travel times to the open pit and discharge to surface water features from the MRSA and TMF and are presented in Table 5-12.

Table 5-12 Predicted Groundwater Discharge Rates (m^3/s) from Mine Rock Storage Area and Tailings Management Facility to Receiving Environment at Closure (Pit Full, without Seepage Collection Ditches)

Project Infrastructure	Receptor	Discharge (m^3/s)	Travel Time (years)			Discharge Arriving within 300 years (m^3/s)
			Minimum	Mean	Maximum	
MRSA	Keewatin River	0.000100	103	1,428	39,811	0.000045
	Tributary of Keewatin River (Kee3-B1)	0.001900	1	241	5,943	0.001812
	Open Pit	0.001200	2,363	11,875	61,476	0.000837
	Minton Lake	0.004400	4	4,860	31,355	0.002995
	Cockeram Lake	0.000034	140,017	249,217	648,383	0.000000
TMF	Watercourse connecting Payne Lake and Keewatin River (Kee3-Pay1)	0.000120	141	213	345	0.000117
	Keewatin River	0.000200	103	1,428	39,811	0.000130
	Tributary of Keewatin River (Kee3-B1)	0.003100	1	241	5,943	0.002117
	Open Pit	0.000200	2,363	11,875	61,476	0.000000
	Minton Lake	0.001100	4	4,860	31,355	0.000033
	Cockeram Lake	0.000034	140,017	249,217	648,383	0.000000
	Subsurface Seepage to Fen	0.000146	1	151	1,302	0.000109

As shown on Table 5-12, the groundwater recharge from beneath the TMF discharges primarily to a tributary of the Keewatin River (63%) or to Minton Lake (22%) with smaller contributions to Payne Lake Tributary (2%), Keewatin River (4%), the open pit (4%), and Cockeram Lake (<1%). The mean advective travel times vary from 213 years to the Payne Lake Tributary, to more than 249,000 years to Cockeram Lake. Groundwater recharge from beneath the MRSA discharges primarily to Minton Lake (58%) or Keewatin River Tributary (25%), with the remainder discharging to the open pit (16%), Keewatin River (1%) or Cockeram Lake (<1%). The mean advective travel times vary from 67 years to Keewatin River Tributary to in excess of 230,000 years to Cockeram Lake.

Similarly, the fate of groundwater that recharges beneath the MRSA and TMF with a 2-m perimeter ditch was also determined by conducting particle tracking. The particle traces at closure with collection ditches are presented on Map 28. The particle traces were used to quantify the inflow rates and travel times to the open pit and discharge to surface water features from the MRSA and TMF including the effect of the collection ditches and are presented in Table 5-13.

Table 5-13 Predicted Groundwater Discharge Rates (m^3/s) from Mine Rock Storage Area and Tailings Management Facility to Receiving Environment at Closure (Pit Full, with 2 m Deep Seepage Collection Ditches)

Project Infrastructure	Receptor	Discharge (m^3/s)	Travel Time (years)			Discharge Arriving within 300 years (m^3/s)
			Minimum	Mean	Maximum	
MRSA	Keewatin River	0.000031	87	106	242	0.000031
	Tributary of Keewatin River (Kee3-B1)	0.001521	2	15	368	0.001480
	Open Pit	0.000457	43	271	14,068	0.000441
	Minton Lake	0.001166	4	77	251	0.001166
	Seepage Collection Ditches	0.004400	0	94	613	0.003930
TMF	Watercourse connecting Payne Lake and Keewatin River (Kee3-Pay1)	0.000003	163	937	2,428	0.000002
	Keewatin River	0.000100	89	217	2,155	0.000117
	Tributary of Keewatin River (Kee3-B1)	0.002400	2	244	4,834	0.002187
	Open Pit	0.000200	941	6,520	56,425	0.000000
	Minton Lake	0.000600	5	872	63,590	0.000474
	Cockeram Lake	0.000100	29,130	87,622	231,790	0.000000
	Seepage Collection Ditches	0.001497	1	248	835	0.000498

As shown on Table 5-13, the seepage collection ditches are predicted to capture 30% and 58% of the overall seepage from the TMF and MRSA. The groundwater recharge from beneath the TMF with ditches discharges primarily to a tributary to Keewatin River (49%) or Minton Lake (12%) with smaller contributions to Payne Lake Tributary (<1%), Keewatin River (2%), the open pit (4%), or Cockeram Lake (2%). The mean advective travel times vary from 240 years to the Keewatin River Tributary, to more than 249,000 years to Cockeram Lake. Groundwater recharge from beneath the MRSA with ditches discharges primarily to Minton Lake (15%) or Keewatin River Tributary (20%), with the remainder discharging to the open pit (6%), or Keewatin River (<1%). The mean advective travel times vary from 67 years to Keewatin River Tributary to in excess of 230,000 years to Cockeram Lake.

Given the long flow paths for seepage from the MRSA and TMF, the proportion of seepage arriving at a receiver within 300 years is provided for reference in Table 5-12 and Table 5-13. Three hundred years travel time was used as a threshold for input to the water balance model (Stantec 2020d), which had a 300-year run time.

5.4.2.3 Sensitivity of Groundwater Discharge to Recharge

A sensitivity analysis was conducted to assess the potential effect of an increase or decrease in the future recharge rate on groundwater discharge to the receiving environment. The sensitivity analysis consisted of two scenarios where the recharge was adjusted as a 25% increase and a 25% decrease from the calibrated, baseline recharge value for each recharge zone. Table 5-14 presents the recharge values used in the sensitivity scenarios compared to the baseline recharge value.

Table 5-14 Sensitivity Analysis Recharge Scenarios

Scenario	Recharge
Baseline (calibration)	120
25% decrease	90
25% increase	150

The predicted groundwater discharge to the receiving environment for closure are presented in Table 5-15 for the baseline recharge rate, the 25% increase, and 25% decrease in recharge rate without the effect of the seepage collection ditches. The relative percent difference in groundwater discharge to watercourses and lakes is less than 20%, and generally less than 10%, when comparing the 25% change in recharge with the calibrated model recharge for the closure scenario, except for Payne Lake, Keewatin River, and the Watercourse from East Pond to Tributary of Keewatin River (Kee3-B2-A1). The sensitivity analysis suggests groundwater discharge to Payne Lake, Keewatin River, and Kee3-B2-A1 is sensitive to a 25% decrease in modelled recharge compared to the calibrated model recharge value. For the 25% increase in recharge sensitivity scenario, the relative percent difference in groundwater discharge to watercourses and lakes was less than 20% except for Kee3-B2-A1. The results of the sensitivity analysis indicate the groundwater discharge to watercourses and lakes is relatively insensitive to a 25% increase in modelled recharge and sensitive to a 25% decrease in modelled discharge for Payne Lake, Keewatin River, and Kee3-B2-A1.

Table 5-15 Sensitivity Analysis of Groundwater Discharge to Recharge – Closure (Pit Full, without Seepage Collection Ditches)

Notes: 1. Positive value represents flow from groundwater to surface water Negative value represents flow from surface water to groundwater				

5.5 PREDICTION CONFIDENCE

The approach used in model simulations completed for this Project was to incorporate conservative assumptions for predicting effects that may result from the Project. This report presents the assumptions made in developing these conservative predictions and discusses the high level of confidence in these predictions.

The modelling was conducted using an EPM approach. As discussed in Section 4.0, this is appropriate based on the regional scale of the modelling and considering that flow was predicted to occur primarily through the shallow weathered bedrock, which is highly fractured, and therefore behaves like a porous medium.

Groundwater recharge rates at the MRSA, TMF and historical MRSA to the receiving environment are conservatively “over predicted” in two ways. First, the results from modelling conducted without the presence of the seepage collection system are used to predict groundwater flows to the receiving environment and to inform the environmental effects assessment. Second, all of the recharge applied within the MRSA, TMF and historical MRSA are assumed to be carried through to the final receptors.

The groundwater flow modelling was conducted using a model calibrated to water levels and baseflow targets to establish baseline conditions. Predictions made using the model are based on several conservative assumptions to reduce the influence of uncertainty in the predictions. Therefore, the confidence in the predictions made using the model is considered high.

6.0 CONCLUSIONS

Hydrogeology modelling was conducted to identify changes to groundwater levels and flow pathways to inform the assessment of potential effects of the LLGP on groundwater and surface water resources at the MacLellan site. The modelling was conducted using FEFLOW and was calibrated to baseline conditions within acceptable industry standards.

The construction and operation of the open pit will require the open pit to be dewatered. The dewatering of the open pit will result in the drawdown of the water table by up to 1.0 m over an area extending approximately 800 m south of the open pit. As dewatering progresses, the average annual groundwater inflow rate increases from 0.006 m^3/s with the starter pit at the end of construction to 0.041 m^3/s with the open pit at the end of operation.

The dewatering of the open pit and mounding of the water table in the vicinity of the TMF will also result in changes to groundwater discharge conditions in watercourses and lakes located near the open pit and TMF. Groundwater discharge to most surface water features will increase as a result of mounding of the water table in the vicinity of the TMF which increases the hydraulic gradient toward these features. A small number of surface water features, such as Kee3-B2-A1, will lose flow to groundwater recharge as a result of the dewatering operations.

Groundwater discharge to surface water features associated with Project facilities represents a minor component of the overall surface water flow systems. The installation of a seepage collection system around the TMF and new MRSA is predicted to capture up to 30% and 58% of seepage from these features, respectively. The modelling results will be considered in the assessment of potential effects on the receiving environment.

9.0 LIMITATIONS

This Technical Modelling Report entitled Lynn Lake Gold Project Hydrogeological Assessment – MacLellan Site was prepared by Stantec Consulting Ltd. ("Stantec") for the account of Alamos Gold Inc. (the "Client") to support the approvals and permitting process for the Lynn Lake Gold Project in Lynn Lake, Manitoba. In connection thereto, this document may be reviewed and used by the federal and provincial government agencies participating in the approvals and permitting process in the normal course of their duties; and stakeholders may provide comment as part of the regulatory approvals process. Except as set forth in the previous sentence, any reliance on this document by any third party for any other purpose is strictly prohibited. The material in it reflects Stantec's professional judgment in light of the scope, schedule and other limitations stated in the document and in the contract between Stantec and the Client. The opinions in contents of the document are based on conditions and information existing at the time the document was published and do not take into account any subsequent changes. In preparing the document, Stantec did not verify information supplied to it by others. Any unauthorized use that a third party makes of this document is the responsibility of such third party. Such third party agrees that Stantec shall not be responsible for costs or damages of any kind, if any, suffered by it or any other third party as a result of decisions made or actions taken based on unauthorized use of this document.

MCFN	Marcel Colomb First Nation
MOECC	Ontario Ministry of the Environment and Climate Change
MECP	Ontario of the Ministry of Environment, Conservation and Parks
MHA	Manitoba Herps Atlas
MRSA	mine rock storage area
Mt	million tonnes
MWSQG	Manitoba Water Quality Standards, Objectives and Guidelines
NOAEL	no observed adverse effects level
NO_2	nitrogen dioxide
ORNL	Oak Ridge National Laboratory
oz	ounces
PAG	potentially acid generating
PAH	polyclic aromatic hydrocarbon
PEF	potency equivalency factor
PEL	probable effect level
PEST	parameter estimation code
PM	particulate matter
$PM_{2.5}$	particulate matter less than 2.5 um diameter
the Project	the Lynn Lake Gold Project
RAA	Regional Assessment Area
RIAQG	Residential Indoor Air Quality Guideline
RMS	root mean squared
ROC	receptor of concern
RIVM	National Institute for Public Health and the Environment, The Netherlands
RQ	risk quotient

SARA	Species at Risk Act
SAR	Species at Risk
SF	slope factor
SOCC	Species of Conservation Concern
SO_2	sulfur dioxide
SQG	soil quality guideline
SR	screening ratio
SRC	serious risk concentration
TC	tolerable concentration
TDI	tolerable daily intake
TDR	technical data report
TMR	technical modelling report
TMF	tailings management facility
TRV	toxicological refence value
UCLM	upper confidence limit of the mean
UR	unit risk
USDA	United States Department of Agriculture
US EPA	United States Environmental Protection Agency
VC	Valued Component
VOC	volatile organic compound

1.0 INTRODUCTION

The Lynn Lake Gold Project (LLGP; or "the Project") consists of two primary deposit sites, which are both located near Lynn Lake, Manitoba: the 'Gordon' site and the 'MacLellan' site. Alamos Gold Inc. (Alamos) intends to construct (redevelop), operate and eventually close/reclaim open pit gold mines at both these historical mine sites. The Gordon site is located approximately 55 kilometres (km) east of Lynn Lake, Manitoba (by vehicle), and the MacLellan site is located approximately 8 km northeast of Lynn Lake (by vehicle) (Map 1, Appendix A). Lynn Lake is located approximately 820 km northwest of Winnipeg.

This human health and ecological risk assessment (HHERA) was completed to support the assessment of human health and ecological effects as part of the environmental assessment for the Project.

The construction, operation, and closure of the Project have the potential to alter baseline conditions with respect to the concentrations of chemicals in the air, soil, water, and biota near the Project. These changes to the environment have the potential to adversely affect the health of human receptors and ecological receptors (terrestrial and aquatic wildlife, and communities of fish, vegetation, and invertebrates). The HHERA characterizes the change in exposure to project-related chemicals that human and ecological receptors may experience between baseline (existing) and future conditions, to quantify the potential change to human health and ecological risk that may be attributed to the Project.

The methods and guidance prescribed by Health Canada (Health Canada 2019a, 2012, 2010a) were used to assess the human health risks, while those provided by the Canadian Council of Ministers of the Environment (CCME) and the Federal Contaminated Sites Action Plan (FCSAP), were used to assess the ecological health risk. This approach is intended to protect the health of people and ecological receptors, which rely on the viability of the local environment and ecological resources within the local assessment area (LAA) /regional assessment area (RAA) of the Project (which are the same area for the Project).

The information presented in this HHERA applies baseline environmental quality data to establish baseline conditions for human and ecological health. Modelled future conditions are applied to characterize scenarios associated with the Project. The environmental data representing baseline and future scenarios are presented in the Valued Component (VC) sections and associated baseline reports, technical data reports, and modelling reports for atmospheric environment, groundwater, surface water, fish and fish habitat, vegetation and wetlands, and wildlife and wildlife habitat.

The conclusions in this HHERA report regarding human health risk are presented in the human health VC, while the conclusions regarding ecological risk to terrestrial receptors are presented in the wildlife and wildlife habitat VC.

The HHERA is supported by seven appendices: Appendix A – Maps; Appendix B – Baseline Data; Appendix C – ProUCL Outputs; Appendix D – Ubiquotous Elements; Appendix E – Example Calculations, Dermal RAF, Uptake Factors; Appendix F – HHRA Outputs; and Appendix G – ERA Outputs.

1.1 PROJECT DESCRIPTION

The Project components include the development of new mine infrastructure at the MacLellan site, including an open pit, a central ore milling and processing plant, associated infrastructure, ore and overburden stockpiles, mine rock storage areas (MRSAs), and a tailings management facility (TMF). At the Gordon site, new infrastructure will be limited to the open pit, ore and overburden stockpiles, a MRSA, and minor supporting infrastructure for equipment storage and maintenance. There will be no tailings storage or milling at the Gordon site.

The Project has three phases: construction, operations, and decommissioning/closure. The construction phase includes site preparation, physical construction, equipment installation, pre-production, and commissioning. Construction is expected to take approximately two years to complete (Years -2 and -1). The operations phase includes ore and mine rock extraction, ore processing, and waste management. The operations phase (starting in Year 1) and is expected to take approximately 6 years at the Gordon site (5 years of active ore and mine rock extraction and an extra year of materials transfer to the MacLellan site for ore processing) and 13 years to complete at the MacLellan site. Active reclamation/closure is expected to take approximately 5-6 years to complete at each site. It will be followed by approximately 10 years of post-closure monitoring and years of pit filling (approximately 11 years at the Gordon site and approximately 21 years at the MacLellan site).

2.0 HUMAN HEALTH AND ECOLOGICAL RISK ASSESSMENT METHODS

The HHERA evaluates the health risk to human and ecological receptors from their exposure to chemicals in environmental media (e.g., air, soil, water, and biota). The HHERA consists of two components: a human health risk assessment (HHRA) and an ecological risk assessment (ERA). The HHRA characterizes the short-term (acute) and long-term (chronic) health risk to people, while the ERA characterizes the potential chronic risk to a species population (e.g., meadow voles), a community of multiple species (e.g., soil invertebrate community), or an individual within a species (applicable to rare and endangered species).

In the context of an environmental assessment for major infrastructure projects, the HHERA evaluates the potential change in health risk to people and ecological receptors that may occur between baseline environmental conditions and future conditions, during the various phases of the Project. Baseline environmental conditions may be based on historical monitoring data, measured data collected during baseline studies, or modelled data. Future conditions are based on modelled data that reflects predicted environmental conditions during Project construction phase, operations phase, decommissioning, reclamation, closure and post-closure.

The HHERA considers three scenarios or cases in evaluating the potential changes in human and ecological health risks. These include:

1) Baseline Case: evaluates the existing exposures and health risks based on the measured chemical concentrations in environmental media (air, soil, water, sediment, plants, benthic invertebrates and

fish). Chemical concentrations for wild meat (e.g. moose) and, soil invertebrates are estimated based upon measured concentrations of chemicals in other media.

2) Future Case: evaluates the future health risks based on the predicted chemical concentrations in environmental media, as determined through detailed modelling from other valued component chapters (e.g. air quality, water quality). These modelling results are used to predict the future chemical concentrations in exposure media that human and ecological receptors are exposed to (i.e. air, water, soil, sediment, vegetation, wild meat, fish, soil invertebrates and benthic invertebrates)

3) Project Alone Case: evaluates health risks associated with exposure to predicted chemical concentrations in environmental media that are attributable only to project activities (i.e. these do not consider the contribution that Baseline Case concentrations make to overall exposure). Project Alone Case concentrations are used in the HHRA to evalute the potential incremental increase in lifetime cancer risk that would be associated with the release of carcinogenic chemicals from the Project.

The change in health risk from Baseline Case to Future Case during the various phases of the Project is the basis for determining whether the Project may result in an unacceptable risk to human or ecological health.

The following sections describe the underlying concepts and approach to conducting an HHERA that is prescribed by Health Canada, the CCME, and the FCSAP.

2.1 COMPONENTS OF HEALTH RISK

All chemicals have the potential to cause adverse health effects to biological organisms. The presence of health risk depends on three factors:

1. The presence of a human or ecological receptor (i.e., receptor)

2. The presence of a COPC with inherent toxicity

3. The exposure pathway and the degree of human or ecological receptor exposure to a chemical.

As illustrated in Figure 2-1, if all three factors of health risk interact (i.e., a receptor is exposed to a chemical hazard), a risk may exist. The degree of adverse health risk depends on other factors such as the exposure dose or concentration, exposure duration, and the inherent toxicity of the chemical to the human or ecological receptor.

If one or more factors(s) is absent, there would be no potential health risk. Also, if a receptor is exposed to a chemical, but the chemical is inherently non-toxic, then there is no potential risk.

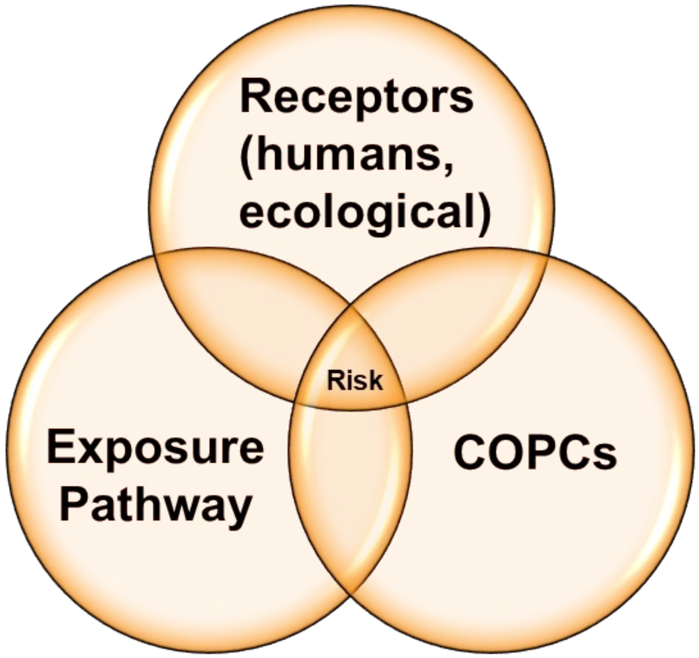

Figure 2-1 Considerations for a Quantitative HHERA (after Health Canada 2019a)

2.2 RISK ASSESSMENT APPROACH AND FRAMEWORK

This HHERA was conducted according to accepted risk assessment methodologies and follows guidance published and endorsed by regulatory agencies such as Health Canada, the CCME, and the FCSAP. This approach is consistent with previous projects that have been reviewed by the Impact Assessment Agency of Canada. The HHRA applies the following guidance for assessing human health for an environmental assessment:

- Guidance for Evaluating Human Health Impacts in Environmental Assessment: Human Health Risk Assessment (Health Canada 2019a).
- Guidance for Evaluating Human Health Impacts in Environmental Assessment: Human Health Risk Assessment: Air Quality (Health Canada 2017a).
- Guidance for Evaluating Human Health Impacts in Environmental Assessment: Human Health Risk Assessment: Country Foods (Health Canada 2017b).
- Guidance for Evaluating Human Health Impacts in Environmental Assessment: Human Health Risk Assessment: Drinking and Recreational Water Quality (Health Canada 2016a).

The HHRA guidance applicable to federal contaminated sites in Canada was also considered as needed, including:

- Federal Contaminated Sites Risk Assessment in Canada, Part I: Guidance on Human Health Risk Preliminary Quantitative Risk Assessment (PQRA), Version 2.0 (Health Canada 2012).
- Federal Contaminated Sites Risk Assessment in Canada, Part V: Guidance on Complex Human Health Detailed Quantitative Risk Assessment For Chemicals (DQRACHEM) (Health Canada 2010a).
- Federal Contaminated Site Risk Assessment in Canada: Supplemental Guidance on Human Health Risk Assessment for Country Foods (HHRAFoods) (Health Canada, 2010c).
- Federal Contaminated Sites Risk Assessment in Canada, Part II: Health Canada Toxicological Reference Values (TRVs) and Chemical-Specific Factors Version 2.0 (Health Canada 2010b).

The HHERA applies the following guidance for assessing ecological risk:

- A Framework for Ecological Risk Assessment—Canadian Council of Ministers of the Environment (CCME 1996).
- Ecological Risk Assessment Guidance Document – Canadian Council of Ministers of the Environment (CCME 2020).

Federal Contaminated Sites Action Plan (FCSAP) Guidance documents considered included:

- FCSAP Ecological Risk Assessment Guidance (FCSAP 2012).
- FCSAP Module 3: Standardization of Wildlife Receptor Characteristics (FCSAP 2012).
- FCSAP Module 6: Ecological Risk Assessment for Amphibians on Federal Contaminated Sites (FCSAP 2019).

The basic risk assessment framework includes the following fundamental stages: site characterization, problem formulation, toxicological assessment, exposure assessment, risk characterization, and uncertainty assessment. Each component is discussed below:

- The **Site Characterization** stage includes a review of existing biophysical, chemical, and land use information completed in support of this EA and identifies the information that is relevant to the HHERA. The identification of chemicals of potential concern (COPC) is presented in this stage followed by the modelled predictions of chemical concentrations in biotic and abiotic environments.
- The **Problem Formulation** stage is an information gathering and interpretation stage that is used to focus the HHERA on the primary areas of concern for the Project. Problem formulation defines the nature and scope of the risk assessment, permits practical boundaries to be placed on the overall scope, and confirms that the HHERA is directed at the key areas and issues of concern related to

the Project emissions. The data gathered provide information regarding the physical layout and characteristics of the assessment area (e.g., the LAA), possible exposure pathways, potential human and ecological receptors, and other specific areas or issues of concern.

- The **Toxicity Assessment** stage involves the selection of toxicity reference values (TRVs) and the identification of regulatory benchmarks for each COPC as appropriate. Toxicity is the potential for a chemical to produce damage, permanent or temporary, to the structure or functioning of the receptor's body. With the exception of community receptors, the toxicity of a chemical depends on the amount of chemical taken into the body (referred to as the "dose") and the duration of exposure (i.e., the length of time the receptor is exposed to the chemical). For community receptors (e.g. plants, benthinc invertebrates, fish) the toxicity depends on the concentration of COPC in the media where the receptors live. For example, for benthic invertebrates, the toxicity depends on the concentration of the COPC in sediment. For each COPC, there is a specific dose and duration of exposure necessary to produce a toxic effect in a given receptor. TRVs are published by provincial, federal or international (e.g., United States Environmental Protection Agency [US EPA]) agencies.

- The **Exposure Assessment** stage builds on the receptor and exposure pathway identification completed in the problem formulation stage. For each COPC, exposures are estimated for each receptor for each of the exposure pathways that are relevant for that receptor. The rate of exposure to chemicals may be expressed as a dose, which is the amount of chemical taken in per body weight per unit time (e.g., microgram (µg) of chemical per kilogram (kg) body weight per day), or as a concentration in the exposure pathway (e.g., when considering health risks to people from the inhalation of COPC, the rate of exposure would be the chemical concentration in air) or environmental media. Exposures are estimated for Baseline Case and Future Case. For carcinogenic COPC, exposures are also estimated for the Project Alone Case.

- The **Risk Characterization** stage involves assessing qualitatively and quantitatively the potential risk to receptors from exposure to COPC. The risk characterization compares the results of the exposure assessment with the TRV established in the toxicity assessment to quantify the level of health risk associated with the predicted exposures. Within an EA framework, the health risks associated with the Future Case are compared to the health risks associated with Baseline Case to provide the context for how the Project may affect health.

- The **Uncertainty Assessment** is used to identify the uncertainties associated with the data used in the assessment and predicts how these uncertainties may influence the final risk estimates and conclusions. Uncertainties may exist in numerous areas including the collection and analysis of samples, estimates of exposure, derivation of TRV and the assumptions used when professional judgment is applied. Understanding how the uncertainties can influence the exposure and risk estimated for Baseline Case and Future Case conditions provides an indication of the confidence that can be placed on the risk assessment conclusions.

Overall, in risk assessment the industry standard is to overstate, rather than understate, potential health risks. Regulatory guidance supports use of a conservative approach (one that overestimates exposures and toxicological responses) when assessing potential health risks for both human and ecological receptors. This conservative approach has been maintained in the assessment of potential human health and ecological risks for the Project.

3.0 SITE CHARACTERIZATION

Site characterization provides the context for how the Project could affect the environment in a manner that could influence human or ecological health risk. This includes the spatial and temporal boundaries the study areas for the HHERA, a summary of the environmental setting, and the receptor locations used to evaluate human health and ecological health risks.

3.1 SPATIAL AND TEMPORAL BOUNDARIES

3.1.1 Spatial Boundaries

There are three distinct spatial boundaries applied in the HHERA. The Project Development Area (PDA), Local Assessment Area (LAA), and Regional Assessment Area (RAA) as shown in Map 1, Appendix A.

The PDA encompasses the Project footprint and a 30-meter buffer around its perimeter. The Project footprint includes the areas where project activities would take place, the anticipated area of direct physical disturbance associated with construction and operation activities. The PDA includes the access roads, the open pits, mine rock storage areas, overburden stockpiles, and ore stockpiles at the Gordon and MacLellan sites; and the tailings management facility and ore milling and processing plant at the MacLellan site. The PDA does not include Provincial Road 391 that connects the Gordon and MacLellan sites.

The LAA is defined as a 50 km by 28 km area centered on the Project and includes both the Gordon and MacLellan sites as shown in Map 1, Appendix A. The LAA encompasses the area in which Project-related environmental effects (direct or indirect) can be predicted or measured with a level of confidence that allows for assessment; and in which there is a reasonable expectation that those potential environmental effects in the LAA could be of potential concern to human health. The RAA represents the area where environmental effects from past, present, or reasonably foreseeable future projects may have cumulative effects to human health. Consistent with the Atmospheric VC, the LAA for the Project is the same area as the RAA, therefore refence to the LAA in this report includes both the LAA and the RAA.

The LAA for the HHERA considered, and is the combined spatial boundaries of, the Atmospheric Environment VC and the Surface Water VC, because the future environmental conditions used to predict effects to human and ecological health are based on modelled future conditions from these other VCs. The LAA is further divided into the Gordon region and MacLellan region to characterize the potential effect to human and ecological health separately. The boundaries of each region are identified on Map 1, Appendix A.

3.1.2 Temporal Boundaries

The temporal boundaries for the Project consist of the following phases.

- Construction (i.e., site preparation, physical construction/equipment installation, pre-production, and commissioning) is is anticipated to take approximately 2 years to complete. Some limited pre-production may occur during this period. Project construction activities will be carried out concurrently at both mine sites.
- Operation (i.e., ore and mine rock extraction, processing, and waste management) and is expected to take approximately 13 years to complete.
  - Mining operations are expected to commence at both sites in Year 1. Mining at the Gordon site will be undertaken for six years while mining at the MacLellan site will be undertaken for the entire life of the Project (i.e., 13 years).
  - The ore stockpiled during mine operations (both sites) will provide feedstock to the ore milling and processing plant during the operations phase.
- Decommissioning/closure is scheduled to begin in Year 6 at the Gordon site and in Year 14 at the MacLellan site, and is expected to take approximately 5-6 years to complete at each site. It will be followed by approximately 10 years of post-closure monitoring and between 11 and 21 years of pit filling (for the Gordon and MacLellan sites, respectively).

3.2 ENVIRONMENTAL SETTING

The Project is located in northern Manitoba, near the Town of Lynn Lake. The landscape is dominated by vegetation communities typical of the boreal forest. Within and immediately surrounding the Project are forested areas, wetlands and lakes. Existing land uses around the Project include residential, traditional and recreational uses. Residential uses are concentrated in the communities of Lynn Lake and the Black Sturgeon Reserve. The lands surrounding these communities are used for traditional land uses and recreational activities.

The Project is in the Boreal Shield Ecozone, Churchill River Upland Ecoregion, and Reindeer Lake Ecodistrict (Smith et al. 1998), which is characterized by black spruce-dominated forests on mineral soils and in poorly drained peatlands. Tamarack (*Larix laricina*) is typical on wetter peatland sites, while drier sites are forested white birch (*Betula papyrifera*), jack pine, and occasionally white spruce (*Picea glauca*). Jack pine (*Pinus banksiana)* stands occur on upland sites, while white birch is found throughout the Ecodistrict. Field surveys documented 200 plant species within the LAA/RAA.

The Project is in the High Boreal wetland region, which is characterized by permafrost and non-permafrost wooded bogs and patterned fens (Halsey et al. 1997). An estimated 37% of the High Boreal wetland region is covered in wetlands, comprised of (in order of dominance): permafrost wooded bogs, wooded fens with internal lawns, patterned open fens, non-patterned open fens, and wooded fens with internal lawns, along with small percentages of swamps and marshes. Eleven wetland types have been recorded within the LAA/RAA.

Based on information from provincial and federal databases, satellite imagery, peer-reviewed literature, telephone interviews with local land users, and motion-triggered cameras, the LAA/RAA is known to support a wide range of mammals including muskrat (*Ondatra zibethicus*), moose (*Alces alces*), Northern river otter (*Lontra canadensis*), American mink (*Mustela vision*), meadow vole (*Microtus pennsylvanicus*), snowshoe hare (*Lepus americanus*), ermine (*Mustela erminea*), red fox (*Vulpes vulpes*), black bear (*Ursus americanus*), and deer mouse (*Peromyscus maniculatus*) (FCSAP 2012). Moose and black bear are some of the important game species harvested by First Nations and local resource users.

Based on the Manitoba Breeding Bird Atlas (MB BBA 2019), 198 bird species have the potential to breed in the general region of the LAA/RAA. Among them, 62 are waterbirds, 4 are upland game birds, 18 are raptors, and 114 are passerines (i.e., songbirds) or near-passerines (e.g., woodpeckers). The full list of the 198 observed and potentially present bird species is in the Bird Baseline Technical Data Report for the Project. Among these species, a number are proposed by CCME and FCSAP as possible receptors to use in ERA mallard (*Anas platyrhynchos*), spotted sandpiper (*Actitus macularia*), lesser scaup (*Aythya affinis*), common merganser (*Mergus merganser*), bald eagle (*Haliaeetus leucocephalus*), great blue heron (*Ardea herodias*), Common loon (*Gavia immer*), ruffed grouse (*Bonasa umbellus*), spruce grouse (*Dendragapus canadensis*), barn swallow (*Hirundo rustica*), red-tailed hawk (*Butro jamaicensis*), and American robin (*Turdus migratorius*) (FCSAP 2012, CCME 2020).

The LAA/RAA lies within four subwatersheds of the broader Granville Lake Watershed: Hughes River, Lower Keewatin River, Lower Lynn River, and Cockeram Lake. The Hughes River Subwatershed contains large lakes such as Ellystan Lake, White Owl Lake, Swede Lake, Simpson Lake, Farley Lake, and Gordon Lake. Most lakes in the LAA/RAA are shallow (<3 m) with soft substrates (e.g., sand or muck). Hard substrates (e.g., boulders or cobbles) are less common but present in some locations. Aquatic vegetation and cover in the littoral zone is abundant in most of the lakes in the LAA/RAA. Stream habitats are generally low gradient, interspersed with short cascades that do not generally create barriers to migration. Beavers are active in the LAA/RAA and their dams present seasonal or temporary barriers to fish passage on several tributaries to the rivers and lakes.

Seventeen fish species are known to be present in the lakes and streams near the Gordon and MacLellan sites based on field surveys from 2015 to 2018. Small-bodied fish species are most diverse in streams and large lakes. Brook stickleback (*Culaea inconstans*) were the most widespread small bodied species and the only one present in small, shallow lakes. Other small-bodied species were ninespine stickleback (*Pungitius pungitius*), log perch (*Percina caprodes*), trout perch (*Percopsis omiscomaycus*), emerald shiner (*Notropis atherinoides*), spottail shiner (*Notropis hudsonius*), longnose dace (*Rhinichthys cataractae*), lake chub (*Couesius plumbeus*), and slimy sculpin (*Cottus cognatus*). Large-bodied fish species were northern pike (*Esox lucius*), walleye (*Sander vitreus*), yellow perch (Perca flavescens), lake whitefish (*Coregonus clupeaformis*), burbot (*Lota lota*), cisco (*Coregonus artedi*), white sucker (*Catostomus commersoni*), and longnose sucker (*Catostomus catostomus*). Larger lakes, such as Cockeram Lake, typically support a greater diversity of fish and fish habitat than smaller lakes in the LAA/RAA. Northern pike are the most widespread large-bodied species in the LAA/RAA, while brook stickleback are the most widespread small-bodied species.

The Gordon site was a former open pit gold mine between 1996 and 1999. The Gordon site went through reclamation after closure, and the site currently consists of a 15 km gravel access road, a bridge across the Hughes River, two capped mine rock storage areas, two capped overburden storage areas, and two water-filled open pits. The buildings and infrastructure from historical operations have been removed. The Gordon site is in the headwaters of a tributary to the Hughes River watershed, and no large rivers flow through the area. Farley Creek, the outlet of Farley Lake, is the largest stream potentially affected by the Project. Short cascades and a proliferation of beaver dams present barriers to fish passage during most flow conditions in several of the streams near the Gordon site.

The MacLellan site was a former underground gold and silver mine that operated between 1986 and 1989. Since closure, the site has been in a care and maintenance phase, with very little reclamation completed. The site currently consists of a 4.6-km gravel access road, power transmission line (abandoned pole line), and infrastructure from the former underground mine, such as head frame, hoist house and shaft, access ramp, maintenance and other storage buildings, core shack and core racks, vent raise, and mine water settling ponds. The Keewatin, Cockeram, and Lynn rivers and their tributaries connect the lakes near the MacLellan site. The Keewatin River is the largest river in the LAA/RAA, connecting Goldsand and Burge lakes upstream of the MacLellan site to Cockeram Lake downstream of the mine site. The Lynn River is a tributary to the Keewatin River upstream of Cockeram Lake.

3.3 RECEPTOR LOCATIONS

Air dispersion modelling was used to estimate COPC concentrations in air at 160 receptor locations across the LAA/RAA (45 locations in Gordon region, 114 locations in the MacLellan region, and single central location within the boundaries of the work camp located within the MacLellan PDA; see Map 2, Appendix A). Receptor locations were selected to represent places where receptors are likely to be present and could be exposed to emissions from the Project. The selection of receptor locations was based on considerations of land use and on input from local communities. Locations included residential developments, commercial and institutional buildings, hunting and/or fishing camps, and potential indigenous use locations. Information related to locations used for traditional purposes was used to select receptor locations where Indigenous persons may be present. This includes locations used for hunting, trapping, fishing, plant gathering, camping/shelter as well as cultural and spiritual areas. The receptor locations are identified on Map 1 (Appendix A). The locations of potential indigenous receptors were informed by Alamo's engagement with Indigenous communities and publicly available sources traditional land use information. Due to the length of time required to conduct air quality modeling Indigenous receptors were selected early in the assessment process and represent potential receptor locations rather than individual use sites.

Dust deposition was modelled at the 160 receptor locations to estimate potential metal accumulation in surface soil over the operational life of the Project. This information was used to evaluate changes in metal concentrations in soil that could result in changes in exposures to metals in soil and plants for human and ecological receptors. The ground surface in the work camp will be covered with buildings, pavement or aggregate material. Aggregate is not considered to be soil, and human contact with aggregate material does not result in the same types of exposures that result from human contact with soil. For example: aggregate material consists of stones that are larger in size than soil particles and therefore, aggregate material will not adhere to exposed skin surfaces. In addition, dust deposited on the aggregate material would not be expected to accumulate on the surface. Rather, it would be washed from the surface into the interstitial spaces between the aggregate material by rain and snow. Thus, dust deposition would not contribute to direct contact exposures such as incidental soil ingestion or dermal uptake of contaminants from soil adhered to skin of workers housed at the camp, and deposition of metal has not been evaluated at the work camp receptor location.

For the ERA, potential risks to ecological receptors were assessed for the Gordon region and the MacLellan region separately (Map 1, Appendix A). Unlike the HHRA, these two regions were not further subdivided to assess risk at specific locations. Rather than being location specific, the ERA used an hybrid approach representative of potential upper limit exposures for each media at each region (as further discussed in Section 6.1.7)

3.4 CHEMICALS OF POTENTIAL CONCERN

Chemicals of potential concern are identified as those Project-related chemicals that may be released to the receiving environment, that have the potential to elicit adverse human or ecological health effects. Project activities are predicted to result in emission of the following groups of chemicals:

- Criteria Air Contaminants (CACs) - NO_2, SO_2, and $PM_{2.5}$.
- Hydrogen cyanide (HCN) and diesel particulate matter (DPM).
- Volatile organic compounds (VOCs) including acetaldehyde, benzene, 1,3-butadiene, ethylbenzene, formaldehyde, propionaldehyde, toluene, 2,2,4-trimethylpentane and xylenes.
- Non-carcinogenic and and carcinogenic polycyclic aromatic hydrocarbons (PAHs) bound to particulate from diesel based combustion sources (e.g., trucks). Non-carcinogenic PAHs include acenaphthene, acenaphthylene, anthracene, fluoranthene, flourene, naphthalene, phenanthrene and pyrene. Carcinogenic PAHs include acenaphthene, acenaphthylene, benz(a)anthracene, benzo(a)pyrene B[a]P, benzo(b+j+k) fluoranthene, benzo(ghi)perylene, chrysene, indeno(1,2,3-cd)pyrene and dibenzo(a,h)anthracene. Potential carcinogenic health risks were calculated based on exposure to benzo(a)pyrene total potency equivalents (B[a]PTPE).
- Airborne particulate-bound metals from fugitive dust from ore, waste rock, and tailings. Particulate-bound metals can also deposit on soil.
- Metals from treated effluent or seepage.
- Metals that could potentially be emitted by the Project, and are therefore considered COPC include: antimony, arsenic, barium, beryllium, cadmium, chromium, cobalt, copper, lead, manganese, mercury, molybdenum, nickel, selenium, silver, strontium, thallium, uranium, vanadium, zinc.

Potential Project emissions (i.e., CACs, VOCs, PAHs and metals) were carried forward collectively without additional screening.

The list of chemicals emitted by the Project was based on the following:

- Review of the Project design.
- Review of mineralogical and trace constituent analysis of the ore, waste rock and overburden.
- Review of air contaminants included in the National Pollutant Release Inventory for gold mines.
- Review of air contaminants with Canadian Ambient Air Quality Standards (CAAQS) that may be emitted by the Project.
- Review of air contaminants emitted from vehicle tailpipe exhaust.

Routine laboratory parameters such as alkalinity, hardness and hydroxide and select inorganics (such as aluminum, bismuth, calcium, iron, lithium, magnesium, potassium and titanium), though measured, were not considered as COPC because they are generally regarded as being innocuous or non-toxic or there is insufficient toxicological information on these compounds to assess potential toxicity. These parameters were not included in the screening. Further rationale for excluding these elements is provided in Appendix D (Ubiquitous Elements).

4.0 BASELINE AND FUTURE EXPOSURE POINT CONCENTRATIONS

Potential health risks related to exposure to a COPC in a given media (e.g., soil) depends on the concentration of the COPC in that media. Baseline Case concentrations were estimated using measured and/or modelled data depending on the media. Future Case concentrations were estimated using Baseline Case concentrations and the changes predicted to occur as a result of Project activities.

To evaluate the potential health risks associated with COPC from the Project, the concentrations of COPC in each of the environmental media to which human and ecological receptors may be exposed, was determined for each of the assessed scenarios (i.e., Baseline Case, Project Alone Case (carcinogenic exposures only), and Future Case). These concentrations are called exposure point concentrations (EPCs) and are used to calculate exposures for human and ecological receptors.

Where measured baseline data were available/applicable, the EPCs were typically based on the 95 percent (%) upper confidence limit of the mean (UCLM). The 95% UCLMs represent reasonably expected and spatially distributed COPC exposure concentrations for human and ecological receptors. The 95% UCLMs were calculated using US EPA ProUCL software (US EPA 2015), version 5.1. The ProUCL outputs are provided in Appendix C (ProUCL Data Outputs); these outputs also contain summary statistics. Where there were insufficient data to determine a 95% UCLM (i.e., less than ten samples (US EPA 2015), COPC concentrations were represented by the maximum measured concentration. Additional details related to the selection of EPCs including the treatment of non-detects are provided in Appendix C.

Baseline Case EPCs were estimated using measured and/or modelled data depending on the media. Baseline Case concentrations in air, soil, terrestrial vegetation, small mammals, sediment and fish were based on samples collected from the Gordon and MacLellan regions. Baseline EPCs for surface water were based on the maximum 12-month running average of the modelled concentrations for the Expected modelling scenario (Stantec 2020b and 2020c). Where measured baseline data were available for biological tissues (e.g., for terrestrial vegetation, fish, etc.), these values were used in place of modelled values for the Baseline Case. Where measured baseline data were not available for biological tissues (i.e., soil invertebrates, aquatic plants, benthic invertebrates and wild meat), Baseline Case concentrations were estimated using standard modelling approaches including the use of uptake factors. The equation used to calculate metal COPC concentrations in a biological tissue from either a soil or water concentration (herein referred to as the generalized equation) is as follows:

$$EPC_j = EPC_i \times UP_{ij} \qquad \text{Equation 4-1}$$

Where:

EPC_j = Exposure point concentration in target biotic tissue *j* (e.g., plants or fish, mg/kg wet weight)

EPC_i = Exposure point concentration in measured media *i* (e.g., soil and/or surface water, in mg/kg dry weight or in mg/L)

UP_{ij} = Uptake Factor from environmental medium *i* to target biota tissue *j* (environmental medium and biotic tissue dependent). Depending on the metal COPC and the media, uptake factors were either based on linear relationships, resulting in a single value, or non-linear relationships, where the value of the uptake factor depends on the exposure point concentration.

For Project Alone and/or Future Case, the EPCs used in the HHERA were based on the results of the predictive air dispersion and deposition modelling (Stantec 2020a) and the predictive water quality modelling (Stantec 2020b; 2020c).

Future concentrations of metal COPC in terrestrial vegetation and soil invertebrates were estimated based upon Future Case concentrations of metal COPC in soil as predicted by the air dispersion and deposition modelling.

Future concentrations of metal COPC in aquatic plants, benthic invertebrates, fish and sediment were estimated using the predictive concentrations from surface water modelling. The metal COPC concentrations in surface water were based on treated effluent released from the Project as well as groundwater seepage from tailings, deposition and baseline surface water concentrations.

Future Case concentrations in wild meat were estimated using Future Case concentrations in soil, surface water, and food (e.g., vegetation, invertebrates).

Predicted changes in COPC concentrations in soil and water, as a result of the Project, were used to predict changes in both modelled and measured data. In order to properly compare modelled Future Case concentrations in tissue, to measured Baseline Case concentrations, it was necessary to reconcile the measured and model-estimated values using a proportional increase approach. This was accomplished using the following process. First, modelled Baseline Case concentrations were calculated using Baseline Case concentrations in soil and/or water and literature-based uptake factors. Modelled Future Case concentrations were then calculated using predicted Future Case concentrations in soil and or water and the same uptake factors. The ratio of the modelled Future Case concentrations and the modelled Baseline Case concentrations were then multiplied by the measured Baseline Case concentrations to predict the Future Case concentration in vegetation, small mammals, sediment and fish tissue.

In summary, this proportioning approach for estimating Future Concentrations of metal COPC was used for the following media:

- Terrestrial vegetation (including coniferous and deciduous vegetation, berries and Labrador tea) – estimated based on predicted change in soil concentrations.
- Small mammals – estimated based on predicted change in soil concentrations.
- Fish Tissue – estimated based on predicted change in surface water concentrations.
- Sediment – estimated based on predicted change in surface water concentrations.

4.1 AIR

Baseline Case concentrations for select CAC and COPC were based on the following:

- Baseline Case concentrations for $PM_{2.5}$ and dustfall were based on samples collected as part of the LLGP baseline ambient air quality monitoring program between June 18, 2016 and October 9, 2016. Ambient air quality monitoring locations are provided in Map 2, Appendix A.
- Baseline Case concentrations SO_2 and NO_2 were based on actual 2018 ambient air quality monitoring results from the NAPS station in Fort Smith, NWT (the 90th percentile of hourly measurements). Fort Smith is also a remote location like Lynn Lake and located approximately 700 km to the northwest of the LAA.
- No Baseline Case concentrations were available for DPM, HCN, metals, VOCs or PAHs. Given the remoteness of the LAA, low population density, and limited industrial activity, baseline concentrations of these chemicals are assumed to be negligible.
- Baseline Case concentrations were assumed to be consistent throughout the LAA, therefore the same Baseline Case concentrations were adopted for both the Gordon region and the MacLellan region.

Future Case concentrations were based on the results of air dispersion modelling during the operation period. Airborne concentrations were modelled for operation only, as emissions during construction and decommissioning, reclamation, closure, and post-closure are substantively lower than those of operation (Stantec 2020a).

The modelling was conducted for 45 receptor locations in the Gordon region and 115 receptor locations in the MacLellan region (1 receptor location in the work camp and 114 receptor locations within the MacLellan region outside the MacLellan PDA). Receptor locations are provided on Map 1, Appendix A. Future Case concentrations were calculated for 1-hr, 24-hr and annual average time periods, where applicable. In some cases, EPCs were based on a specific statistic to meet requirements for comparison to a particular guideline. These statistics are provided in Table 4-1 to Table 4-15**.**

4.1.1 CAC

Baseline and Future Case concentrations of CACs at the Gordon region, MacLellan region and at the work camp are provided in Table 4-1 to Table 4-3. CACs include SO_2, NO_2 and $PM_{2.5}$.

Table 4-1 1-hour Concentrations of SO_2 and NO_2

COPC	Baseline Case (µg/m³)	Future Case		
		Gordon Region	MacLellan Region	Work Camp
		Maximum 1-hour (µg/m³)	Maximum 1-hour (µg/m³)	Maximum 1-hour (µg/m³)
SO_2 [a]	6.00E+00	4.47E+01	3.62E+01	9.62E+01

NOTES:
[a] Based on the Maximum 5-year Average Concentrations
[b] Based on the Maximum 3-year Average Concentrations

4.1.2 DPM

Baseline and Future Case concentrations of DPM are provided in Table 4-4 and Table 4-5. The Future Case concentrations of DPM are comprised of Project Alone Case concentrations only, as Baseline Case concentrations were not available for Gordon region and MacLellan region and given the remoteness of the LAA, low population density and limited industrial activity, baseline concentration of DPM is assumed to be negligible.

Table 4-4 2-hour Concentration of DPM during Project Operations

4.1.6 Metals

Baseline and Future Case concentrations of non-carcinogenic and carcinogenic metals are provided in Table 4-14 and Table 4-15, respectively. The Future Case concentrations of metals are comprised of Project Alone concentrations only, as Baseline Case concentrations were not available. Future case concentrations of antimony, barium and strontium were not modelled because these metals are not expected to be emitted to the air by the Project.

Table 4-14 Non-Carcinogenic Exposure Point Concetrations for Residential Receptors and Indigenous Receptors – Metals

4.2 SOIL

Baseline Case concentrations in soil were based on samples collected from within the LAA. Samples were identified as either coming from the Gordon region or the MacLellan region. Sample locations are provided in Map 3, Appendix A.

Deposition was modelled for the operation phase when release of rock and ore dust is expected to occur. Although it is anticipated that dust would be released from the Project during the construction phase, this dust will be composed of overburden and the metal concentrations in this material would not be expected to differ from metal concentrations in existing surface soils. Thus, dust deposition during the construction phase would not be expected to alter metal concentrations in surface soil. Therefore, the construction phase was not included in the prediction of the change in metal concentrations in surface soil over the operational life of the Project.

The specific dust deposition rates predicted at each of the selected deposition receptor locations were used to estimate the Future Case concentrations of metal COPC in soil. Future Case concentrations in soil were assumed to be based on 5 years of active ore extraction operation for the Gordon site and 13 years of active ore extraction operation for the MacLellan site. The incremental increase in metal concentration in soil resulting from rock and ore dust deposition assumed that metal accumulation in the soil would occur over the life of mine and that there would be no loss of metal from the soil (e.g., from runoff). The exposure point concentration in soil was calculated based on the 95% UCLM deposition rate for a region, assuming the deposited metals mix with the top 2 cm of soil, which is the mixing depth for untilled soil recommended by the US EPA (2005).

4.2.1 Gordon Region

Baseline metal concentrations in soil for the Gordon region were based on 28 samples and three field duplicates collected in 2015 and 2016. The 95% UCLM concentration was adopted as the Baseline Case concentration for each metal throughout the Gordon region. Deposition was modelled for the 45 receptor locations. The 95% UCLM deposition rate was used to estimate future concentrations in soil for the Gordon region. Baseline Case and Future Case EPCs for metal COPC for the Gordon region are provided in Table 4-16.

4.2.2 MacLellan Region

Baseline metal concentrations in soil for the MacLellan region were based on 25 samples and three field duplicates collected in 2015 and 2016. The 95% UCLM concentration was adopted as the Baseline Case concentration for each metal throughout the MacLellan region. Deposition was modelled for the 115 receptor locations. The 95% UCLM deposition rate (outside the permanent work camp) was used to estimate future concentrations in soil in the MacLellan region. Baseline Case and Future Case EPCs for metal COPC in soil are provided in Table 4-16.

Table 4-16 Exposure Point Concentrations in Soil – Metals

Vanadium	1.22E+01	1.22E+01	5.57E+00	5.67E+00
Zinc	4.67E+01	4.68E+01	8.30E+01	8.40E+01

4.3 TERRESTRIAL PLANTS

Terrestrial vegetation consisted of traditional plants, coniferous and deciduous vegetation and garden produce were collected from the LAA. Sample locations are provided in Map 3, Appendix A. The results of the traditional plants and the garden produce were used to predict risks for humans, while the results of the traditional plants, and coniferous and deciduous vegetation (collectively referred to as wild vegetation) were used to estimate concentrations in tissues of target hunting species and health risks for ecological receptors.

4.3.1 Traditional Plants

Traditional plants including berries and Labrador tea were collected from each region. Details related to the Baseline Case and Future Case concentrations in traditional plants for each region are discussed in Section 4.3.1.1 and Section 4.3.1.2, respectively, and concentrations are provided in Table 4-17.

4.3.1.1 Gordon Region

Baseline Case metal concentrations in traditional plants (i.e., berries and tea) were based on 61 samples and seven field duplicates collected throughout the Gordon region in 2015 and 2016:

- Berries: blueberries (*Vaccinium corymbosum*), bog cranberries (*Vaccimum oxycoccos*), cloud berries (*Rubus chamaemorus*) (n=38).
- Labrador tea (n= 30).

The 95% UCLM concentrations of berries or tea was adopted as the Baseline Case concentration for each metal throughout the Gordon region. Future Case concentrations of metal COPC in vegetation were estimated using Equation 4-1 (relating metal concentrations in vegetation to soil concentrations) and published uptake factors from soil-to-vegetation (Bechtel and Jacobs 1998; Sheppard and Evenden 1988; US EPA 2007). Baseline Case and Future Case EPCs for metal COPC in traditional plants are provided in Table 4-17.

4.3.1.2 MacLellan Region

Baseline Case metal concentrations in traditional plants (i.e., berries and tea) were based on 53 samples and five field duplicates collected throughout the MacLellan region:

- Berries: blueberries, bog cranberries, cloud berries (n=31).
- Labrador tea (n=27).

The 95% UCLM concentration was adopted as the Baseline Case concentration for each metal throughout the MacLellan region. Future Case concentrations of metal COPC in vegetation were estimated using Equation 4-1 (relating elemental concentrations in vegetation to soil concentrations) and published uptake factors from soil-to-vegetation (Bechtel and Jacobs 1998; Sheppard and Evenden 1988; US EPA 2007). Baseline Case and Future Case EPCs for metal COPC in traditional plants are provided in Table 4-17.

Table 4-17 Exposure Point Concentrations in Traditional Plants – Metals

4.3.2 Terrestrial Wild Plants

Terrestrial wild plants including coniferous vegetation (spruce), deciduous vegetation (e.g., aspen, willow, alder, birch), Labrador tea and berries was collected from each region Concentrations in terrestrial wild plants were used in the HHRA to predict concentrations in wild meat, and in the ERA to predict potential health risks for ecological receptors.

4.3.2.1 Gordon Region

Baseline Case metal concentrations in terrestrial plants were based on a combined total of 112 samples (28 coniferous, 23 deciduous, 27 Labrador tea and 34 berry samples) and 13 field duplicates (three coniferous, three deciduous, three Labrador tea and four berry samples) collected throughout the Gordon region in 2015 and 2016. The average of the 95% UCLM concentrations for coniferous vegetation, deciduous plants, Labrador tea and berries was adopted as the Baseline Case concentrations throughout the Gordon region. Future Case concentrations of metal COPC in vegetation were estimated using Equation 4-1 relating elemental concentrations in vegetation to soil concentrations and published uptake factors from soil-to-vegetation (Bechtel and Jacobs 1998; Sheppard and Evenden 1988; US EPA 2007). Baseline Case and Future Case EPCs for metal COPC in soil are provided in Table 4-18.

4.3.2.2 MacLellan Region

Baseline Case metal concentrations in terrestrial plants were based on a combined total of 93 samples (23 coniferous, 17 deciduous, 25 Labrador tea and 28 berry samples) and nine field duplicates (two coniferous, two deciduous, two Labrador tea, and three berry samples) collected throughout the MacLellan region in 2015 and 2016. The average of the 95% UCLM concentrations for coniferous vegetation,deciduous vegetation, Labrador tea and berries was adopted as the Baseline Case concentrations throughout the MacLellan region. Future Case concentrations of metal COPC in vegetation were estimated using Equation 4-1 relating elemental concentrations in vegetation to soil concentrations and published uptake factors from soil-to-vegetation (Bechtel and Jacobs 1998; Sheppard and Evenden 1988; US EPA 2007). Baseline Case and Future Case EPCs for metal COPC in soil are provided in Table 4-18.

4.3.3 Garden Produce

Garden produce was collected from the MacLellan region, but not the Gordon region. No backyard gardens were identified in the Gordon region.

4.3.3.1 Gordon Region

The concentrations from the MacLellan region will be used to evaluate risk for receptors in the Gordon region. Baseline Case and Future Case EPCs for metal COPC in soil are provided in Table 4-19.

4.3.3.2 MacLellan Region

Baseline Case metal concentrations in backyard garden produce were based on nine samples of backyard garden produce (carrots (3), potatoes (5) and beets (1)) collected from the Town of Lynn Lake (within the MacLellan region) in 2016. The maximum concentration was adopted as the Baseline Case concentration for each metal in backyard garden produce throughout the MacLellan region. Future Case concentrations of metal COPC in vegetation were estimated Equation 4-1 relating elemental concentrations in vegetation to soil concentrations and published uptake factors from soil-to-vegetation (Bechtel Jacobs 1998; Sheppard and Evenden 1988; US EPA 2007).Baseline Case and Future Case EPCs for metal COPC in soil are provided in Table 4-19.

4.4 SMALL MAMMALS

Small mammals were collected from the Gordon region and the MacLellan region. Sampling locations are provided in Map 4, Appendix A.

4.4.1 Gordon Region

Baseline Case metal concentrations in small mammals were based on the maximum concentration of individual metals from three red-backed voles and three deer mice collected in the Gordon region. Future concentrations in small mammals were estimated using the predicted concentrations of COPC in soil and the generalized equation relating elemental concentrations in biota to soil concentrations and using published uptake factors (JWL and IES2008; Sample et al. 1998b; US EPA 2007). Baseline and Future Case EPCs for metal COPC in small mammals are provided in Table 4-20.

4.4.2 MacLellan Region

Baseline Case metal concentrations in small mammals were based on the maximum concentration of individual metals from six red-backed voles collected in the MacLellan region. Future concentrations in small mammals were estimated using the predicted concentrations of COPC in soil and the generalized equation relating elemental concentrations in biota to soil concentrations and using published uptake factors (JWL and IES2008; Sample et al. 1998b; US EPA 2007). Baseline and Future Case EPCs for metal COPC in small mammals are provided in Table 4-20.

4.5 SURFACE WATER

Surface water samples were collected from both the Surface Water LAA for the Gordon site and the MacLellan site. The locations of these samples are provided in Map 5 and Map 6, Appendix A. The results from these samples were used to model Baseline Case concentrations in surface water.

4.5.1 Gordon Region

Baseline Case surface water concentrations for predicting changes in fish tissue were based on the maximum 12-month running average of the modelled baseline surface water concentrations in Swede Lake because it was assumed people in the Gordon region would obtain local fish from Swede Lake. Baseline Case surface water concentrations for predicting risks related to consumption (for both human and ecological receptors) and for predicting Baseline Case concentrations in wild meat were based on the maximum 12-month running averages of modelled Baseline Case surface water concentrations from waterbodies within the Surface Water LAA for the Gordon site (including West Farley Lake, East Farley Lake, Swede Lake, Ellystan Lake and Susan Lake). The latter approach is based on the assumption that human and ecological receptors could potentially consume surface water from multiple lakes throughout the Surface Water LAA for the Gordon site (Stantec 2020b)

Future Case surface water concentrations for predicting changes in fish tissue were based on the maximum 12-month running average surface water concentrations in Swede Lake for the Expected case. Expected case inputs include average and geometric mean concentrations for surface and groundwater, respectively (Stantec 2020b), and is representative of the typical changes in surface water concentrations that may occur as a result of the Project. Future Case concentrations for assessing ingestion and predicting concentrations in wild meat and is based on the maximum 12-month running average surface water concentrations for the Expected case for waterbodies in the Surface Water LAA for the Gordon site. Baseline Case and Future Case EPC for metal COPC in surface water from Swede Lake are provided in Table 4-21, while Baseline Case and Future Case EPC in waterbodies from the Surface Water LAA for the Gordon site are provided in Table 4-21.

4.5.2 MacLellan Region

Baseline Case surface water concentrations for predicting changes in fish tissue were based on the maximum 12-month running average of the modelled baseline surface water concentrations in Cockeram Lake because it was assumed that people in the MacLellan region would obtain local fish from Cockeram Lake. Baseline Case surface water concentrations for predicting risks related to consumption (for both human and ecological receptors) and for predicting Baseline Case concentrations in wild meat were based on the maximum 12-month running averages of modelled Baseline Case surface water concentrations from waterbodies within the Surface Water LAA for the MacLellan site (including Keewatin River, Minton Lake, Cockeram River, Cockeram Lake and a catchment adjacent to and north of the PDA; Stantec 2020c).

Future Case surface water concentrations for predicting changes in fish tissue were based on the maximum 12-month running average surface water concentrations in Cockeram Lake for the Expected case (Stantec 2020c). Future Case concentrations for assessing ingestion and predicting concentrations in wild meat and is based on the maximum 12-month running average surface water concentrations for the Expected case for waterbodies in the Surface Water LAA for the MacLellan site. Baseline Case and Future Case EPC for metal COPC in surface water from Cockeram Lake are provided in Table 4-21, while Baseline Case and Future Case EPC in waterbodies from the Surface Water LAA for the MacLellan site are provided in Table 4-21.

4.6 FISH

Both large bodied and small bodied fish were collected from the Surface Water LAA for the Gordon site and the Surface Water LAA for the MacLellan site. The large bodied fish data were used in the HHRA, while both the large and small bodied fish data were used in ERA. Fish sampling locations are provided in Map 7, Appendix A.

4.6.1 Fish for Human Consumption

Large-bodied fish including northern pike, lake whitefish and walleye were collected for the HHRA as these species are considered representative of fish consumed by local residents and Indigenous people. Metal concentrations in these fish are assumed to be representative of the concentrations in other target fish species. Fish tissues considered for human consumption included liver, carcass and muscle as it was assumed that humans could consume the entire fish.

4.6.1.1 Gordon Region

Based on communication with local residents and Indigenous people, it was assumed that receptors did not harvest fish from Farley Lake (immediately downstream of the Project). Swede Lake is located immediately downstream of Farley Lake and formerly supported a commercial fishery, therefore it is possible that people may obtain a portion of their local fish from Swede Lake. Baseline Case metal concentrations in fish were based on 33 samples each of liver, carcass and muscle samples from large-bodied fish collected from Swede Lake in 2015 and 2016. Fish species included walleye (n=3), Lake whitefish (n=15) and Northern Pike (n=15). The average of the 95% UCLM concentrations of liver, carcass and muscle concentrations was adopted as the Baseline Case concentration for each metal in fish from Swede Lake. The Future Case concentrations for fish were estimated using the predictive concentrations from surface water modelling (for Swede lake). Uptake factors for surface water to fish for predicting Future Case concentrations were obtained from the Canadian Standards Association (CSA 1987), Davis et al. (1993), Lijzen et al. (2001), McGeer et al. (2003), Nussey et al. (1999), and the US EPA (2003c). Baseline Case and Future Case EPCs for metal COPC in large-bodied fish are provided in Table 4-23.

4.6.1.2 MacLellan Region

It was assumed that people in the MacLellan region obtain a portion of their local fish from Cockeram Lake. Baseline Case metal concentrations in fish were based on 29 samples each of liver, carcass and muscle tissue collected from Cockeram Lake in 2015 and 2016. Fish species included walleye n=1), Lake whitefish (n=13) and Northern Pike (n=15). The average of the 95% UCLM concentrations of liver, carcass and muscle concentrations was adopted as the Baseline Case concentration for each metal in fish tissue from Cockeram Lake. The Future Case concentrations for fish were estimated using the predictive concentrations from surface water modelling (for Cockeram Lake). Uptake factors for surface water to fish for predicting Future Case concentrations were obtained from the Canadian Standards Association (CSA 1987), Davis et al. (1993), Lijzen et al. (2001), McGeer et al. (2003), Nussey et al. (1999), and the US EPA (2003c). Baseline Case and Future Case EPCs for metal COPC in large-bodied fish are provided in Table 4-23.

4.6.2 Fish for Ecological Receptors

Small-bodied fish such as spottail shiner and brook stickleback, and large-bodied fish such as northern pike, walleye, lake whitefish and yellow perch were collected for the ERA.

4.6.2.1 Gordon Region

For the ERA, Baseline Case metal concentrations in fish were based on 28 whole body samples from small-bodied fish and 63 muscle samples, 63 liver samples, and 63 carcass samples from large-bodied fish collected throughout the Surface Water LAA for the Gordon region in 2015 and 2016. Fish species include brook stickleback (n= 18), spottail shiner (n=8), yellow perch, (n=2) northern pike (n=45), walleye (n=3), and lake whitefish (n=15). The maximum of the 95% UCLM concentration for whole body, muscle, liver or carcass was considered as the representative baseline EPC for fish. The Future Case concentrations for fish were estimated using the predictive concentrations from surface water modelling. Uptake factors for surface water to fish for predicting Future Case concentrations were obtained from the Canadian Standards Association (CSA 1987), Davis et al. (1993), Lijzen et al. (2001), McGeer et al. (2003), Nussey et al. (1999), and the US EPA (2003c). Baseline and Future Case EPCs for metal COPC in fish consumed by ecological receptors are provided in Table 4-24.

4.6.2.2 MacLellan Region

For the ERA, Baseline Case metal concentrations in fish tissue were based on 39 whole body samples from small-bodied fish and 49 muscle samples, 49 liver samples and 49 carcass samples from large-bodied fish collected throughout the Surface Water LAA for the MacLellan region in 2015 and 2016. Fish species include brook stickleback (n= 30), spottail shiner (n=9), yellow perch, (n=2) northern pike (n=35), walleye (n=1), and lake whitefish (n=13).

The maximum of the 95% UCLM concentration for each metal COPC in the dataset was whole body, muscle, liver or carcass was considered as the representative baseline EPC for fish. The Future Case concentrations for fish were estimated using the predictive concentrations from surface water modelling. Uptake factors for surface water to fish for predicting Future Case concentrations were obtained from the Canadian Standards Association (CSA 1987), Davis et al. (1993), Lijzen et al. (2001), McGeer et al. (2003), Nussey et al. (1999), and the US EPA (2003a). Baseline and Future Case EPCs for metal COPC in fish are provided in Table 4-24.

4.7 SEDIMENT

Sediment samples were collected from the Surface Water LAA for the Gordon site and for the MacLellan site. Sample locations are provided in Map 8, Appendix A.

4.7.1 Gordon Region

Baseline Case metal concentrations in sediment were based on the 48 samples and nine field duplicates collected from various waterbodies throughout the Surface Water LAA for the Gordon site in 2015 and 2016. The 95% UCLM concentration was adopted as the Baseline Case concentration for each metal throughout the Gordon region. Future Case concentrations of metal COPC in sediment were estimated based upon the predicted Future Case concentration in surface water from the various waterbodies with the Surface Water LAA for the Gordon Site and Equation 4-1 for estimating sediment concentrations from surface water concentrations. Where available, uptake factors for water-to-sediment were based on concentration ratios (CR) from Sheppard et al. (2010) which were adjusted to consider site-specific sediment characteristics (e.g., organic carbon and grain-size) and provide the quantity of the available and mineralized metal content in the sediment. For metals not covered by Sheppard et al. (2010), sediment-to-water partition coefficients were obtained from other sources as follows: mercury from CSA (2011 update).

Baseline Case and Future Case EPCs for metal COPC in sediment are provided in Table 4-25.

4.7.2 MacLellan Region

Baseline metal concentrations in sediment were based on the 51 samples and nine field duplicates collected from various waterbodies throughout the Surface Water LAA for the MacLellan site in 2015 and 2016. The 95% UCLM concentration was adopted as the Baseline Case concentration for each metal throughout the MacLellan region. Future Case concentrations of metal COPC in sediment were estimated based upon the predicted Future Case concentration in surface water from the various waterbodies with the Surface Water LAA for the MacLellan site and Equation 4-1 for estimating sediment concentrations from surface water concentrations. Where available, uptake factors for water-to-sediment were based on CR from Sheppard et al. (2010) which were adjusted to consider site-specific sediment characteristics (e.g., organic carbon and grain-size) and provide the quantity of the available and mineralized metal content in the sediment. For metals not covered by Sheppard et al. (2010), sediment-to-water partition coefficients were obtained from other sources as follows: mercury from CSA (2011 update).

Baseline Case and Future Case EPCs for metal COPC in sediment are provided in Table 4-25.

4.8 TERRESTRIAL INVERTEBRATES

Terrestrial invertebrates represent an important food source for small mammals and birds. Earthworms and slugs were the target of baseline sampling programs, but none were observed during collection periods from either the Gordon or MacLellan regions. However, the absence of these organisms from the collection program does not mean that they do not exist in the region. As such, concentrations of COPC in soil invertebrates for both Baseline Case and Future Case were estimated using the baseline and predicted future concentrations of COPC in soil along with Equation 4-1, which relates metal concentrations in biota to soil concentrations and published uptake factors (Sample et al. 1998a; US EPA 2007). Predicted Baseline and Future Case concentrations in terrestrial invertebrates are provided in Table 4-26.

Table 4-26 Exposure Point Concentrations in Soil Invertebrates – Metals

4.9 AQUATIC PLANTS

Baseline sampling for the HHERA was conducted before information on the consumption of aquatic plants as available through the Indigenous and community engagement process. In the absence of local information, the HHERA relied on information contained in the First Nations Food, Nutrition & Environment Study (FNFNES) – Results from Manitoba 2010 (Chan et al. 2012) which did not identify aquatic plants as being consumed. As a result, baseline aquatic vegetation samples were not collected from the Surface Water LAA for the Gordon and Maclellan Sites. Therefore, concentrations of metal COPC in aquatic vegetation for all cases were estimated based upon the measured Baseline Case concentrations of metal COPC in the Surface Water LAA for the Gordon and MacLellan Site. Uptake to aquatic plants was modelled using the Baseline Case concentrations for surface water and Equation 4-1 relating chemical concentrations in vegetation to predicted surface water concentrations, partitioning coefficients, and published uptake factors from surface water-to-vegetation (Bechtel and Jacobs 1998; Sheppard and Evenden 1988; US EPA 2007). The Future Case concentrations for aquatic plants were estimated using the predictive concentrations from surface water modelling. Baseline and Future Case EPCs for metal COPC in aquatic plants are provided in **Table** 4-27.

Table 4-27 Exposure Point Concentrations in Aquatic Plants – Metals

4.10 BENTHIC INVERTEBRATES

Baseline benthic invertebrates were not collected from the Surface Water LAA for the Gordon and MacLellan regions. The concentrations of metal COPC in benthic invertebrates for both Baseline and Future Case were estimated based upon the metal concentration in sediment under each case as well as the generalized equation for estimating benthic invertebrate tissue concentrations from sediment concentrations. Uptake factors for sediment to benthic invertebrates were obtained from Garn et al. (2001), Hamilton et al. (2002), Haus et al. (2007), ORNL (1998), and Welsh and Maughan (1994).The Baseline and Future Case EPCs of metal COPC in benthic invertebrates are provided in Table 4-28.

4.11 WILD MEAT

Wild meat samples were not collected from the LAA. It is generally not considered ethical to sacrifice large mammals for an EA.

Baseline and Future Case metal concentrations in wild meat (moose, snowshoe hare, beaver, grouse and mallard) were modelled using generalized equations from the US EPA (2005a,b). The generalized equation used to calculate COPC concentrations in wild meat that will be consumed by humans is:

$$C_{meat} = \Big(\big(F_V \times Q_{V(meat)} \times P_V\big) + \big(F_S \times Q_{S(meat)} \times C_s\big) + \big(F_{Sed} \times Q_{Sed(meat)} \times C_{Sed}\big) + \big(F_{Food} \times Q_{Food(meat)} \times C_{Food}\big) + \big(F_W \times Q_{W(meat)} \times C_W\big)\Big) \times B_{a(meat)} \times MF$$

where:

C_{meat} = Concentration of COPC in meat tissue (mg/kg wet weight);

F_V = Fraction of vegetation from site (conservatively set at 100%; unitless), could be comprised of terrestrial vegetation (coniferous or decididuous), berries or aquatic vegetation.;

$Q_{V(meat)}$ = Quantity of vegetation (including terrestrial and/or aquatic vegetation) ingested by animal (kg dry weight/day);

P_V = Concentration of COPC in vegetation (mg/kg dry weight);

F_S = Fraction of soil from site (conservatively set at 100%; unitless);

$Q_{S(meat)}$ = Quantity of soil ingested by animal (kg dry weight/day);

C_S = Concentration of COPC in soil (mg/kg dry weight);

F_{Sed} = Fraction of sediment from site (conservatively set at 100%; unitless);

$Q_{Sed(meat)}$ = Quantity of sediment ingested by animal (kg dry weight/day);

C_{Sed} = Concentration of COPC in sediment (mg/kg dry weight);

F_{Food} = Fraction of food from site (conservatively set at 100%; unitless);

$Q_{Food(meat)}$ = Quantity of food ingested by animal (kg dry weight/day);

C_{Food} = Concentration of COPC in food (mg/kg dry weight);

F_W = Fraction of water from site (conservatively set at 100%; unitless);

$Q_{W(meat)}$ = Quantity of water ingested by animal (L/day);

C_W = Concentration of COPC in surface water (mg/L);

$B_{a(meat)}$ = COPC-specific bio-transfer factor for animal (day/kg wet weight); and

MF = Metabolic factor (set at 1.0; unitless).

The target hunting species were conservatively assumed to spend an entire lifetime within either the Gordon or MacLellan region and not range into other areas that would be subject to different (lesser) rates of deposition. As such, the fractions of soil, terrestrial vegetation, terrestrial invertebrates, surface water, aquatic plants, benthic invertebrates and sediment that the target species would consume within the Gordon and MacLellan regions have conservatively been set at 100%. It was also conservatively assumed that all metal COPC are 100% bioavailable and are not metabolized (i.e., metabolic factor of 1). The intake rates of soil, terrestrial vegetation, terrestrial invertebrates, surface water, aquatic plants, benthic invertebrates and sediment for the moose, snowshoe hare, beaver, spruce grouse and mallard were estimated using the animals' body weights and the equations provided in US EPA (2005a,b). The body weights of each species and the intake rates for each media are provided in the receptor profiles in Section 6.1.2 of the ERA.

Uptake factors from the primary literature and intake rates for predicting animal tissue concentrations are available for beef cattle. In accordance with US EPA (2005a,b) guidance, to predict the uptake of COPC into moose, snowshoe hare, beaver, spruce grouse and mallard, the beef uptake factor is adjusted based on the relative lipid content of these animals. The fat content of the moose, snowshoe hare and beaver were assumed to be 10%, and the fat content for the spruce grouse and mallard were assumed to be 14% (based on fat content of a chicken), in contrast to 19% for the beef cattle as per Shultz *et al.* (1994), Stephenson (2003), and Knott *et al.* (2005).

Concentrations of COPC in wild meat under baseline conditions were estimated using the equations and uptake factors described above, as well as the baseline concentrations for soil, terrestrial vegetation, terrestrial invertebrates, surface water, aquatic plants, benthic invertebrates and sediment. The concentrations under future conditions were estimated using the same equations and uptake factors and the predicted future concentrations in these media.

Baseline Case and Future Case EPCs for metal COPC in wild meat from the Gordon region and MacLellan regions are provided in Table 4-29 to Table 4-32.

Table 4-29 Baseline Exposure Point Concentrations in Wild Meat from the Gordon Region– Metals

4.12 SUMMARY OF APPROACHES USED TO ESTIMATE EXPOSURE POINT CONCENTRATIONS

A summary of the approaches used to estimate exposure point concentrations for each media are provided in Table 4-33.

Table 4-33 Summary of Approaches used to Estimate Exposure Point Concentrations

Media	Sample Information	Approach Used to Estimate Baseline Case Concentrations	Approach Used for Future Case Concentrations
Air	Baseline Case concentrations of SO_2 and NO_2 were based on actual 2018 ambient air quality monitoring results from the NAPS station in Fort Smith, NWT (the 90th percentile of hourly measurements). Fort Smith is also a remote location like Lynn Lake and located approximately 700 km to the northwest of the LAA. Baseline Case concentrations for $PM_{2.5}$ and dustfall were based on the average concentrations of samples collected as part of the LLGP baseline ambient air quality monitoring program between June 18, 2016 and October 9, 2016.	90th Percentile of hourly measured concentrations of NO_2 and SO_2 at Fortsmith, NWT. Average of measured concentrations of $PM_{2.5}$ and dustfall at LLGP.	Future Case EPCs of CACs (SO_2, NO_2, $PM_{2.5}$) were based on maximum predicted CAC concentrations derived using air dispersion modelling for receptor locations in the Gordon region, MacLellan region and at a single receptor location in work camp. Future Case EPCs of non-metal COPC such as DPM, HCN, VOC, PAHs and Metals in air were based on maximum predicted emissions of COPC at each receptor location during project operations. Since baseline concentrations were not measured for DPM, HCN, VOC, PAHs and metals, the predicted concentrations of COPC for Project Alone Case (project operations) were considered as Future Case concentrations when calculating non-carcinogenic risks for human receptors in Section 5.4.3.
Soil	A total of 33 samples (30 samples and 3 field duplicates) were collected in the Gordon region. A total of 26 samples (23 samples + 3 field duplicates) were collected in the MacLellan region.	95th UCLM	Predicted based on the 95% UCLM Baseline Case concentration in soil for each region and the 95% UCLM deposition rate for each region.
Terrestrial Plants	A total of 132 vegetation samples (119 samples + 13 field duplicates) were collected in the Gordon LAA. A total of 104 samples (95 samples + 9 field duplicates) were collected in the MacLellan LAA. Vegetation samples consisted of traditional plants (i.e., berries and Labrador tea), browse (includes both coniferous and deciduous vegetation) and garden produce.	95th UCLM for each type of vegetation	Predicted using uptake equations (soil to vegetation), Baseline Case vegetation concentrations and Future Case concentrations in soil.
Small Mammals	A total of six specimens were collected in Gordon region. A total of six specimens were collected in the MacLellan region.	Maximum	Predicted using uptake equations and Future Case soil concentrations.
Surface water	Baseline and Future Case concentrations were modelled. The water model was calibrated using the conentraitons from the Gordon region and the MacLellan region.	Modelled (obtained from Surface Water Assessment)	Modelled using the maximum 12-month running average surface water concentrations. Baseline Case and Future Case concentrations in Swede Lake and Cockeram Lake were used to estimate changes in fish tissue concentrations. Whle Future Case concentrations in surface water from the Surface Water LAA for the Gordon site and the MacLellan site were used to predict concentrations in wild meat and for the ERA.

Table 4-33 Summary of Approaches used to Estimate Exposure Point Concentrations

Media	Sample Information	Approach Used to Estimate Baseline Case Concentrations	Approach Used for Future Case Concentrations
Fish Tissue	A total of 28 whole body samples from small-bodied fish and 189 liver, muscle and carcass samples from large-bodied fish were collected in the Gordon region. A total of 39 whole body samples from small-bodied fish and 147 liver, muscle and carcass samples from large-bodied fish were collected in the MacLellan region.	Average of the 95th UCLM of the liver, flesh and carcass samples	Predicted using uptake equations (surface water to fish tissue) and Future Case surface water concentration.
Sediment	A total of 48 samples and 9 field duplicates were collected from waterbodies in the Gordon region. A total of 51 samples and nine field duplicates were collected from the MacLellan region.	95th UCLM	Predicted using uptake equations Future Case concentrations in surface water.
Terresrial Invertebrates	Concentrations of metal COPC in soil invertebrates for all cases were estimated using uptake equations and soil concentrations.	Modelled based on soil concentrations.	Predicted using uptake equations and Future Case soil concentrations.
Aquatic Plants	Concentrations of metal COPC in aquatic vegetation for all cases were estimated based upon the use of uptake equations (water to aquatic plant) and surface water concentrations.	Predicted based on Baseline Case surface water concentrations.	Predicted using uptake equations and Future Case surface water concentrations.
Benthic Invertebrates	Concentrations of metal COPC in benthic invertebrates for both the Baseline and Future cases were estimated using uptake equations (sediment to benthic invertebrate) and the sediment concentration.	Predicted based on sediment concentrations.	Predicted based on Future Case sediment concentrations.
Wild Meat	Samples of wild meat were not collected from the LAA. Therefore Baseline Case and Future Case concentrations in wild meat were predicted using uptake equations.	Predicted using uptake equations Baseline Case concentrations in soil, surface water, vegetation and food (i.e, soil invertebrates and benthic invertebrates).	Predicted using uptake equations and Future Case concentrations in soil, surface water, vegetation and food.

5.0 HUMAN HEALTH RISK ASSESSMENT

A human health risk assessment is a scientific study that estimates the nature and magnitude of potential adverse health risks in humans following exposure to Project-related chemical emissions. This HHRA assessed interactions between measured or predicted concentrations of COPC in environmental media (i.e., air, soil, water, air, and food items) that may occur due to Project-related emissions, and the potential for these interactions to result in adverse health risks to human receptors exposed to these media.

5.1 PROBLEM FORMULATION

Problem formulation is the first major component of a HHRA and is intended to define key issues that will be further evaluated in a risk assessment. Problem formulation includes the identification of relevant receptors of concern and their characteristics, COPC and exposure pathways that potentially connect the receptors to relevant contaminated environmental media. As the relevant COPC have been identified elsewhere (Section 3.4), the key tasks of the problem formulation step include the following:

- Receptor Identification and Characterization: Identification of the "receptors of concern" which includes the people with the greatest probability of exposure to the COPC and/or those that have the greatest potential sensitivity to the COPC.

- Exposure Pathway Identification: Identification of the means by which COPC move through the environment from a source to a point of contact with people; these exposure pathways are then used to develop the conceptual site model (CSM).

5.1.1 Human Receptors Characterization

Three representative human receptors are evaluated. The Indigenous Receptor and Residential Receptor are assumed to be present in each region, while the Off-Duty Worker Receptor is assumed to be present only at the work camp.

- **Indigenous Receptors** – Includes Indigenous people who may live in either region, but who are assumed to consume higher levels of country foods, harvested from within their region, compared to the Residential Receptors. They are assumed to spend 100% of their time in one of the two regions. This would also apply to Indigenous people who regularly come to the area to harvest food but do not live in either region.

- **Residential Receptors** – Includes non-Indigenous residents who may live in one of the two regions. Residents are assumed to spend 100% of their time in one of the two regions. Residential receptors are assumed to consume less country foods than the Indigenous Receptor.

- **Off-Duty Worker Receptors** – Includes Off-Duty Workers present in the permanent work camp at the MacLellan site. This receptor is only evaluated for inhalation exposures, as ingestion exposures are assumed to be comparable to those of the general population because this receptor will not consume country foods, backyard foods or untreated water from the LAA.

Other receptors such as visitors to the LAA are expected to have lower exposures than these receptor groups.

5.1.1.1 General Receptor Assumptions

The following assumptions apply to both the Indigenous Receptors and Residential Receptors:

- Human receptors were assumed to spend 100% of their time within their particular region and no distinction was made between time spent indoors and time spent outdoors. This means that the COPC concentrations in air predicted for each residential receptor location were assumed to be the same indoors and outdoors. This approach assumes that inhalation exposures to COPC happens on a 24-hour per day basis and is not limited to the time a person spends outdoors.

- Human receptors were assumed to be exposed to the EPCs calculated for the appropriate exposure averaging period (e.g. 1-hour, 24-hour, annual average etc.) for each COPC predicted in their region (i.e., Gordon region and MacLellan region).

- The air quality modelling provided dust depostion estimates for each of the 45 recpetor locations in the Gordon region and the 114 receptor locations in the MacLellan region. The deposition estimates for the 45 receptor locations in the Gordon region were used to calulate a 95%UCLM dust depostion estimate for the Gordon region. The deposition estimates for the 114 receptor locaitons in the MacLellan region that outside the PDA, were used to calculate the 95% UCLM dust deposition estimate for the MacLellan region. The 95% UCLM deposition rate for a region was used to estimate dust deposition across that entire region. The approach provides reasonable upper estimates of the potential increases in metal concentrations in soil and therefore, the potential increases in exposures to COPC in soil.

- Human receptors were assumed to potentially obtain drinking water from surface water in their particular region.
- Receptors in a given region were assumed to obtain 100% of wild meat, berries and traditional plants from their region.
- Receptors were assumed to obtain 10% of the fish they consume on a yearly basis from Swede Lake (for Gordon region receptors) or Cockeram Lake (for MacLellan region receptors). This is considered conservative, as information gathered through community and Indigenous engagement suggests that people obtain fish from lakes across the Gordon and MacLellan regions. Thus, assuming that 10% of the fish consumed in a year is harvested from the lakes immediately downstream from the Project will likely over estimated.
- It was assumed that receptors would consume fish muscle (i.e., fillet), fish liver, and fish carcass from their particular region.
- Receptors were assumed to consume backyard garden produce, and it was further assumed that the consumption of backyard garden produce accounted for 10% of the yearly combined intake of root vegetables and other vegetables identified by Health Canada (2012). The assumption that 10% of vegetables are obtained from backyard gardens is consistent with CCME (2006) for residential land use which determined the quantity of produce that could reasonably be produced from a typical

backyard garden in a given growing season. Based on these results, the CCME concluded that backyard produce could account for up to 10% of the total yearly intake of produce.

5.1.1.2 Specific Assumption for the Indigenous Receptors

The following specific assumption applies to Indigenous Receptors:

- The country food consumption rates for the Indigenous Receptor were based on the 95th percentile grams of traditional food per day reported in the First Nations Food, Nutrition & Environment Study (FNFNES) – Results from Manitoba 2010 (Chan et al. 2012).

Ingestion related assumptions for the Indigenous Receptor are summarized in Table 5-1.

5.1.1.3 Specific Assumption for the Residential Receptors

The following specific assumption applies to the Residential Receptors:

- The country food consumption rates for the Residential Receptor were based on the mean grams of traditional food per day reported in Chan et al. (2012).

Ingestion related assumptions for the Indigenous Receptor are summarized in Table 5-1.

5.1.1.4 Specific Assumptions for the Off-Duty Worker Receptor

The following specific assumptions applies to the Off-Duty Worker Receptor:

- Off-Duty Workers are assumed to be present in the camp for 24 hours per day on a 14-days on/14-days off rotation schedule for a total of 26 weeks per year.
- Off-Duty Workers do not consume country foods or untreated water from the LAA.

Table 5-1 Receptor Parameters used in the HHRA

Parameter	Units	Infant	Toddler	Child	Teen	Adult	Reference/Explanation
General Receptor Characteristics – applies to all receptor groups							
Age Range	-	0-6 m	7 m - 4 yrs	5 - 11 yrs	12-19 yrs	>20yrs	Health Canada, 2012
Years within an Age Group	years	0.5	4.5	7	8	60	Health Canada, 2012
Body Weight	kg	8.2	16.5	32.9	59.7	70.7	Health Canada, 2012
Soil Ingestion Rate	g/day	0.02	0.08	0.02	0.02	0.02	Health Canada, 2012
Drinking Water Consumption	L/day	0.3	0.6	0.8	1	1.5	Health Canada, 2012
Skin Surface Area – applies to all receptor groups							
Hands	cm^2	320	430	590	800	890	Health Canada, 2012
Upper & Lower Arms	cm^2	550	890	1480	2230	2500	Health Canada, 2012
Upper & Lower Legs	cm^2	910	1690	3070	4970	5720	Health Canada, 2012
Total	cm^2	1780	3010	5140	8000	9110	Health Canada, 2012
Soil Loading to Skin							
Hands	g/cm^2	1.0E-04	1.0E-04	1.0E-04	1.0E-04	1.0E-04	Health Canada, 2012
Other Surfaces	g/cm^2	1.0E-05	1.0E-05	1.0E-05	1.0E-05	1.0E-05	Health Canada, 2012
Averaged Loading	g/cm^2	2.6E-05	2.3E-05	2.0E-05	1.9E-05	1.9E-05	Calculated as weighted average loading.
Residential Receptors							
Food Ingestion Rates							
Local Wild Meat-Large Mammal	g/day	0.00E+00	5.43E+00	7.98E+00	1.12E+01	1.72E+01	The intake rate for the adult was selected from Chan et al. (2012) for average intake. The intake rates for the remaining age groups were calculated by adjusting the intake rate for the adult from Chan et al. (2012) by the ratio of the intake rate for wild meat for the age group provided by Health Canada (2012) and the intake rate for the adult provided by Health Canada (2012). Residential receptors were assumed to obtain 100% of their wild meat from their respective region.
Local Wild Meat-Small Mammal	g/day	0.00E+00	2.83E-01	4.17E-01	5.83E-01	9.00E-01	

Table 5-1 Receptor Parameters used in the HHRA

Parameter	Units	Infant	Toddler	Child	Teen	Adult	Reference/Explanation
Local Wild Meat-Aquatic Mammals	g/day	0.00E+00	1.42E-01	2.08E-01	2.92E-01	4.50E-01	
Local Wild Meat-Aquatic Birds	g/day	0.00E+00	1.96E+00	2.88E+00	4.04E+00	6.23E+00	
Local Wild Meat-Terrestrial Birds	g/day	0.00E+00	2.27E-01	3.33E-01	4.67E-01	7.20E-01	
Local Fish	g/day	0.00E+00	4.03E-01	7.22E-01	8.49E-01	9.34E-01	The intake rate for the adult was selected from Chan et al. (2012) for average intake. The intake rates for the remaining age groups were calculated by adjusting the intake rate for the adult from Chan et al. (2012) by the ratio of the intake rate for fish for the age group provided by Health Canada (2004) and the intake rate for the adult provided by Health Canada (2004). Receptors are assumed to obtain 10% of there fish intake from local sources. This is considered conservative, as information gathered through community and Indigenous engagement suggests that people obtain fish from lakes across the Gordon and MacLellan regions. Thus, assuming that 10% of the fish consumed in a year is harvested from the lakes immediately downstream from the Project will likely over estimated.
Traditional Plant Intake-Berries	g/day	3.50E+00	3.88E+00	5.84E+00	7.83E+00	7.33E+00	The intake rate for the adult was selected from Chan et al. (2012) for average intake. The intake rates for the remaining age groups were calculated by adjusting the intake rate for the adult from Chan et al. (2012) by the ratio of the intake rate for vegetation (sum of root vegetables and other vegetables) for the age group provided by Health Canada (2012) and the intake rate for the adult provided by Health Canada (2012). Receptors

Table 5-1 Receptor Parameters used in the HHRA

Parameter	Units	Infant	Toddler	Child	Teen	Adult	Reference/Explanation
							were assumed to obtain 100% of their intake of berries from their respective region.
Traditional Plant Intake- Other	g/day	1.19E+00	1.32E+00	1.98E+00	2.66E+00	2.49E+00	The intake rate for the adult was selected from Chan et al. (2012) for average intake. The intake rates for the remaining age groups were calculated by adjusting the intake rate for the adult from Chan et al. (2012) by the ratio of the intake rate for vegetation (sum of root vegetables and other vegetables) for the age group provided by Health Canada (2012) and the intake rate for the adult provided by Health Canada (2012). Receptors were assumed to obtain 100% of their intake of traditional plants from their respective region.
Backyard Produce	g/day	1.55E+01	1.72E+01	2.59E+01	3.47E+01	3.25E+01	The intake rate was based on the sum of the root vegetables and other vegeatbles for each age group provided in Health Canada (2012). Receptors were assumed to obtain 10% of their total intake of vegetables from backyard gardens.
Indigenous Receptor							
Local Wild Meat- Large Mammal	g/day	0.00E+00	1.80E+01	2.65E+01	3.71E+01	5.73E+01	The intake rate for the adult was selected from Chan et al. (2012) for high consumption intake. The intake rates for the remaining age groups were calculated by adjusting the intake rate for the adult from Chan et al. (2012) by the ratio of the intake rate for wild meat for the age group provided by Health Canada (2012) and the intake rate for the adult provided by Health Canada (2012). Receptors were assumed to obtain 100% of their intake of traditional plants from their respective region.
Local Wild Meat- Small Mammal	g/day	0.00E+00	1.56E+00	2.30E+00	3.21E+00	4.96E+00	
Local Wild Meat- Aquatic Mammals		0.00E+00	5.76E-01	8.47E-01	1.19E+00	1.83E+00

Local Wild Meat- Terrestrial Birds	g/day	0.00E+00	6.11E-01	8.98E-01	1.26E+00	1.94E+00	

Table 5-1 Receptor Parameters used in the HHRA

Parameter	Units	Infant	Toddler	Child	Teen	Adult	Reference/Explanation
Local Fish	g/day	0.00E+00	1.57E+00	2.81E+00	3.30E+00	3.63E+00	The intake rate for the adult was selected from Chan et al. (2012) for high consumption intake. The intake rates for the remaining age groups were calculated by adjusting the intake rate for the adult from Chan et al. (2012) by the ratio of the intake rate for fish for the age group provided by Health Canada (2004) and the intake rate for the adult provided by Health Canada (2004). Receptors are assumed to obtain 10% of there fish intake from local sources. This is conservative based on discussions with residents who indicated they typically do not obtain fish from waterbodies in the Gordon region or the MacLellan region.
Traditional Plant Intake-Berries	g/day	1.46E+01	1.62E+01	2.44E+01	3.27E+01	3.06E+01	The intake rate for the adult was selected from Chan et al. (2012) for high consumption intake. The intake rates for the remaining age groups were calculated by adjusting the intake rate for the adult from Chan et al. (2012) by the ratio of the intake rate for vegetation (sum of root vegetables and other vegetables) for the age group provided by Health Canada (2012) and the intake rate for the adult provided by Health Canada (2012). Receptors were assumed to obtain 100% of their intake of berries from their respective region.
Traditional Plant Intake- Other	g/day	4.28E+00	4.75E+00	7.15E+00	9.58E+00	8.97E+00	The intake rate for the adult was selected from Chan et al. (2012) for high consumption intake. The intake rates for the remaining age groups were calculated by adjusting the intake rate for the adult from Chan et al. (2012) by the ratio of the intake rate for vegetation (sum of root vegetables and other vegetables) for the age group provided by Health Canada (2012) and the intake rate for the adult provided by Health Canada (2012). Receptors were assumed to obtain 100% of their intake of traditional plants from their respective region.
Backyard Produce	g/day	1.55E+01	1.72E+01	2.59E+01	3.47E+01	3.25E+01	The intake rate was based on the sum of the root vegetables and other vegeatbles for each age group provided in Health Canada (2012). Receptors were assumed to obtain 10% of their total intake of vegetables from backyard gardens.

NOTE:
[A] Soil ingestion rate includes incidental ingestion of both soil and indoor dust. The concentrations in soil and indoor dust were assumed to be equivalent for risk estimates.

5.1.1.5 Human Receptor Locations

Receptors were assumed to be present in either the Gordon region or the and MacLellan region (Map 1, Appendix A). The exposures for human receptors in each region are evaluated separately because changes to the environment are different between the two regions. Water-related exposures for receptors in the Gordon region are based on exposure to water or aquatic species from the Surface Water LAA for the Gordon site (boundaries provided on Map 1, Appendix A). Water-related exposures for receptors in the MacLellan region are based on exposure to water or aquatic species from the Surface Water LAA for the MacLellan site (boundaries provided on Map 1, Appendix A).

Specific receptor locations selected for air modelling and deposition were selected to represent places where people are likely to be present and could be exposed to emissions from the Project. The selection of receptor locations was based on considerations of land use and on input from local communities. Locations included residential developments, commercial and institutional buildings, hunting and/or fishing camps, and potential indigenous use locations. The locations of potential indigenous receptors were informed by Alamos' engagement with Indigenous communities and publicly available sources traditional land use information. Due to the length of time required to conduct air quality modeling Indigenous receptors were selected early in the assessment process and represent potential receptor locations rather than individual use sites.

5.1.2 Ingestion of Surface Water Pathway- Humans

On occasion, humans could ingest water directly from the lakes located in their particular region; however, based on information gathered through engagement, which indicate that people do not obtain drinking water directly from the lakes in either region, these occurrences are expected to be infrequent. The exceptions are West Lynn Lake, which is the water supply for the town of Lynn Lake. West Lynn Lake is not expected to be affected by the Project, and Hughes Lake, which is used as a source of water for the Black Sturgeon reserve, but it is located outside of the Surface Water LAA for the Gordon site and the water passes through a water treatment system prior to distribution to the community. The average of the predicted Future Case concentrations of metals in lakes in the Gordon region and the MacLellan region were compared to Canadian drinking water guidelines (Table 5-2). Preference was given to guidelines from Health Canada (2019b); in the absence of Health Canada guidelines, guidelines from other jurisdications (e.g., Ontario) were selected. Future Case concentrations of metals in the applicable lakes in the Gordon region and the MacLellan region were less than the apllicable guidelines, suggesting that even if the water were used for consumption, health risks related to metal exposures would be negligible. Health Canada guidance notes that where multiple pathways of epxosure are being evaluated, epxosure to contaminants in drinking and recreational water should be included in the multi-media assessment (Health Canada 2016a). However, the drinking water supplies for the Town of Lynn Lake and Black Sturgeon Reserve will not be affected by Project activities, meaning that the potential human health risks associated with the presence of metals in the drinking water supplies for these communities will not change between Baseline Case and Future Case conditions. In addition, the assessment of potential health risks associated with ingestion and dermal contact exposures, uses a risk acceptability benchmark of 0.2 rather than 1.0, which is consistent with

Health Canada guidance (2019a) when exposures not affected by Project activities are not included in the assessment. Therefore, the ingestion of surface water pathway by humans was not assessed further.

Table 5-2 Screening of Surface Water Against Drinking Water Guidelines

Chemical	Drinking Water Quality Guideline	Gordon Surface Water LAA- Future Case	MacLellan Surface Water LAA- Future Case
	mg/L	mg/L	mg/L

5.1.3 Direct Contact with Sediment-Humans

There are no human health sediment quality guidelines; however, based on Health Canada (2017c), in the absence of guidelines, concentrations in sediment can be comapred to soil quality guidelines protective of human health. With the exception of cobalt from the MacLellan region, vanadium from the Gordon region, and manganese and nickel from the Gordon and MacLellan regions, Baseline Case and Future Case concentrations of metals in sediment are below the applicable soil quality guidelines for protection of human health (Table 5-3). Baseline Case concentrations of the identified metals in sediment exceed the applicable guidelines and the Project-related increases in sediment concentrations from the two regions are predicted to be less than 5%. Humans could come in direct contact with sediment; however, risks related to sediment contact are considered minor. In addiiton, there are no public beaches or areas of shoreline where high intensity activities occur were identified in the Gordon or MacLellan regions and locations where humans could be exposed to sediment are remote and exposure would be infrequent. Overall this supports the conclusion that risks related to direct contact with sediment are minor and were therefore not assessed further.

Table 5-3 Screening of Sediment Against Soil Quality Guidelines

Chemical	Soil Quality Guideline for Human Direct Contact-Residential	Sediment from Gordon Region – Future Case	Sediment from MacLellan Region- Future Case
	mg/kg	mg/kg	mg/kg

5.1.4 Exposure Pathway Screening and Conceptual Site Model

The exposure pathway screening and development of the CSM provide the exposure pathways by which people might be exposed to COPC. In the exposure assessment, the likelihood that human receptors may come into contact with a COPC was evaluated by examining the potential pathway for the movement of a COPC from its source to the eventual point of intake (exposure) by the receptor. For the HHRA, the potential exposure media for human receptors and a pathway-specific rationale for inclusion or exclusion from the HHRA are shown in Figure 5-1. The rationale for the inclusion of each pathway in the HHRA is provided in Table 5-4. In is noted that the Off-Duty Worker receptor was only evaluated for inhalation exposures. The work camp will be covered in buildings, pavement or aggregate material. This aggregate material will not be covered in soil and will remain exposed for the lifetime of the work camp. Aggregate is not considered to be soil, and human contact with aggregate material does not result in the same types of exposures that result from human contact with soil.

Off-Duty Workers will not consume untreated surface water or consume country food from the LAA.

Beginning with the source media (e.g., air, soil, water), the key exposure pathways through which potential dietary items can accumulate COPC and human receptors can become exposed to COPC are summarized in the human health CSM (Figure 5-1).

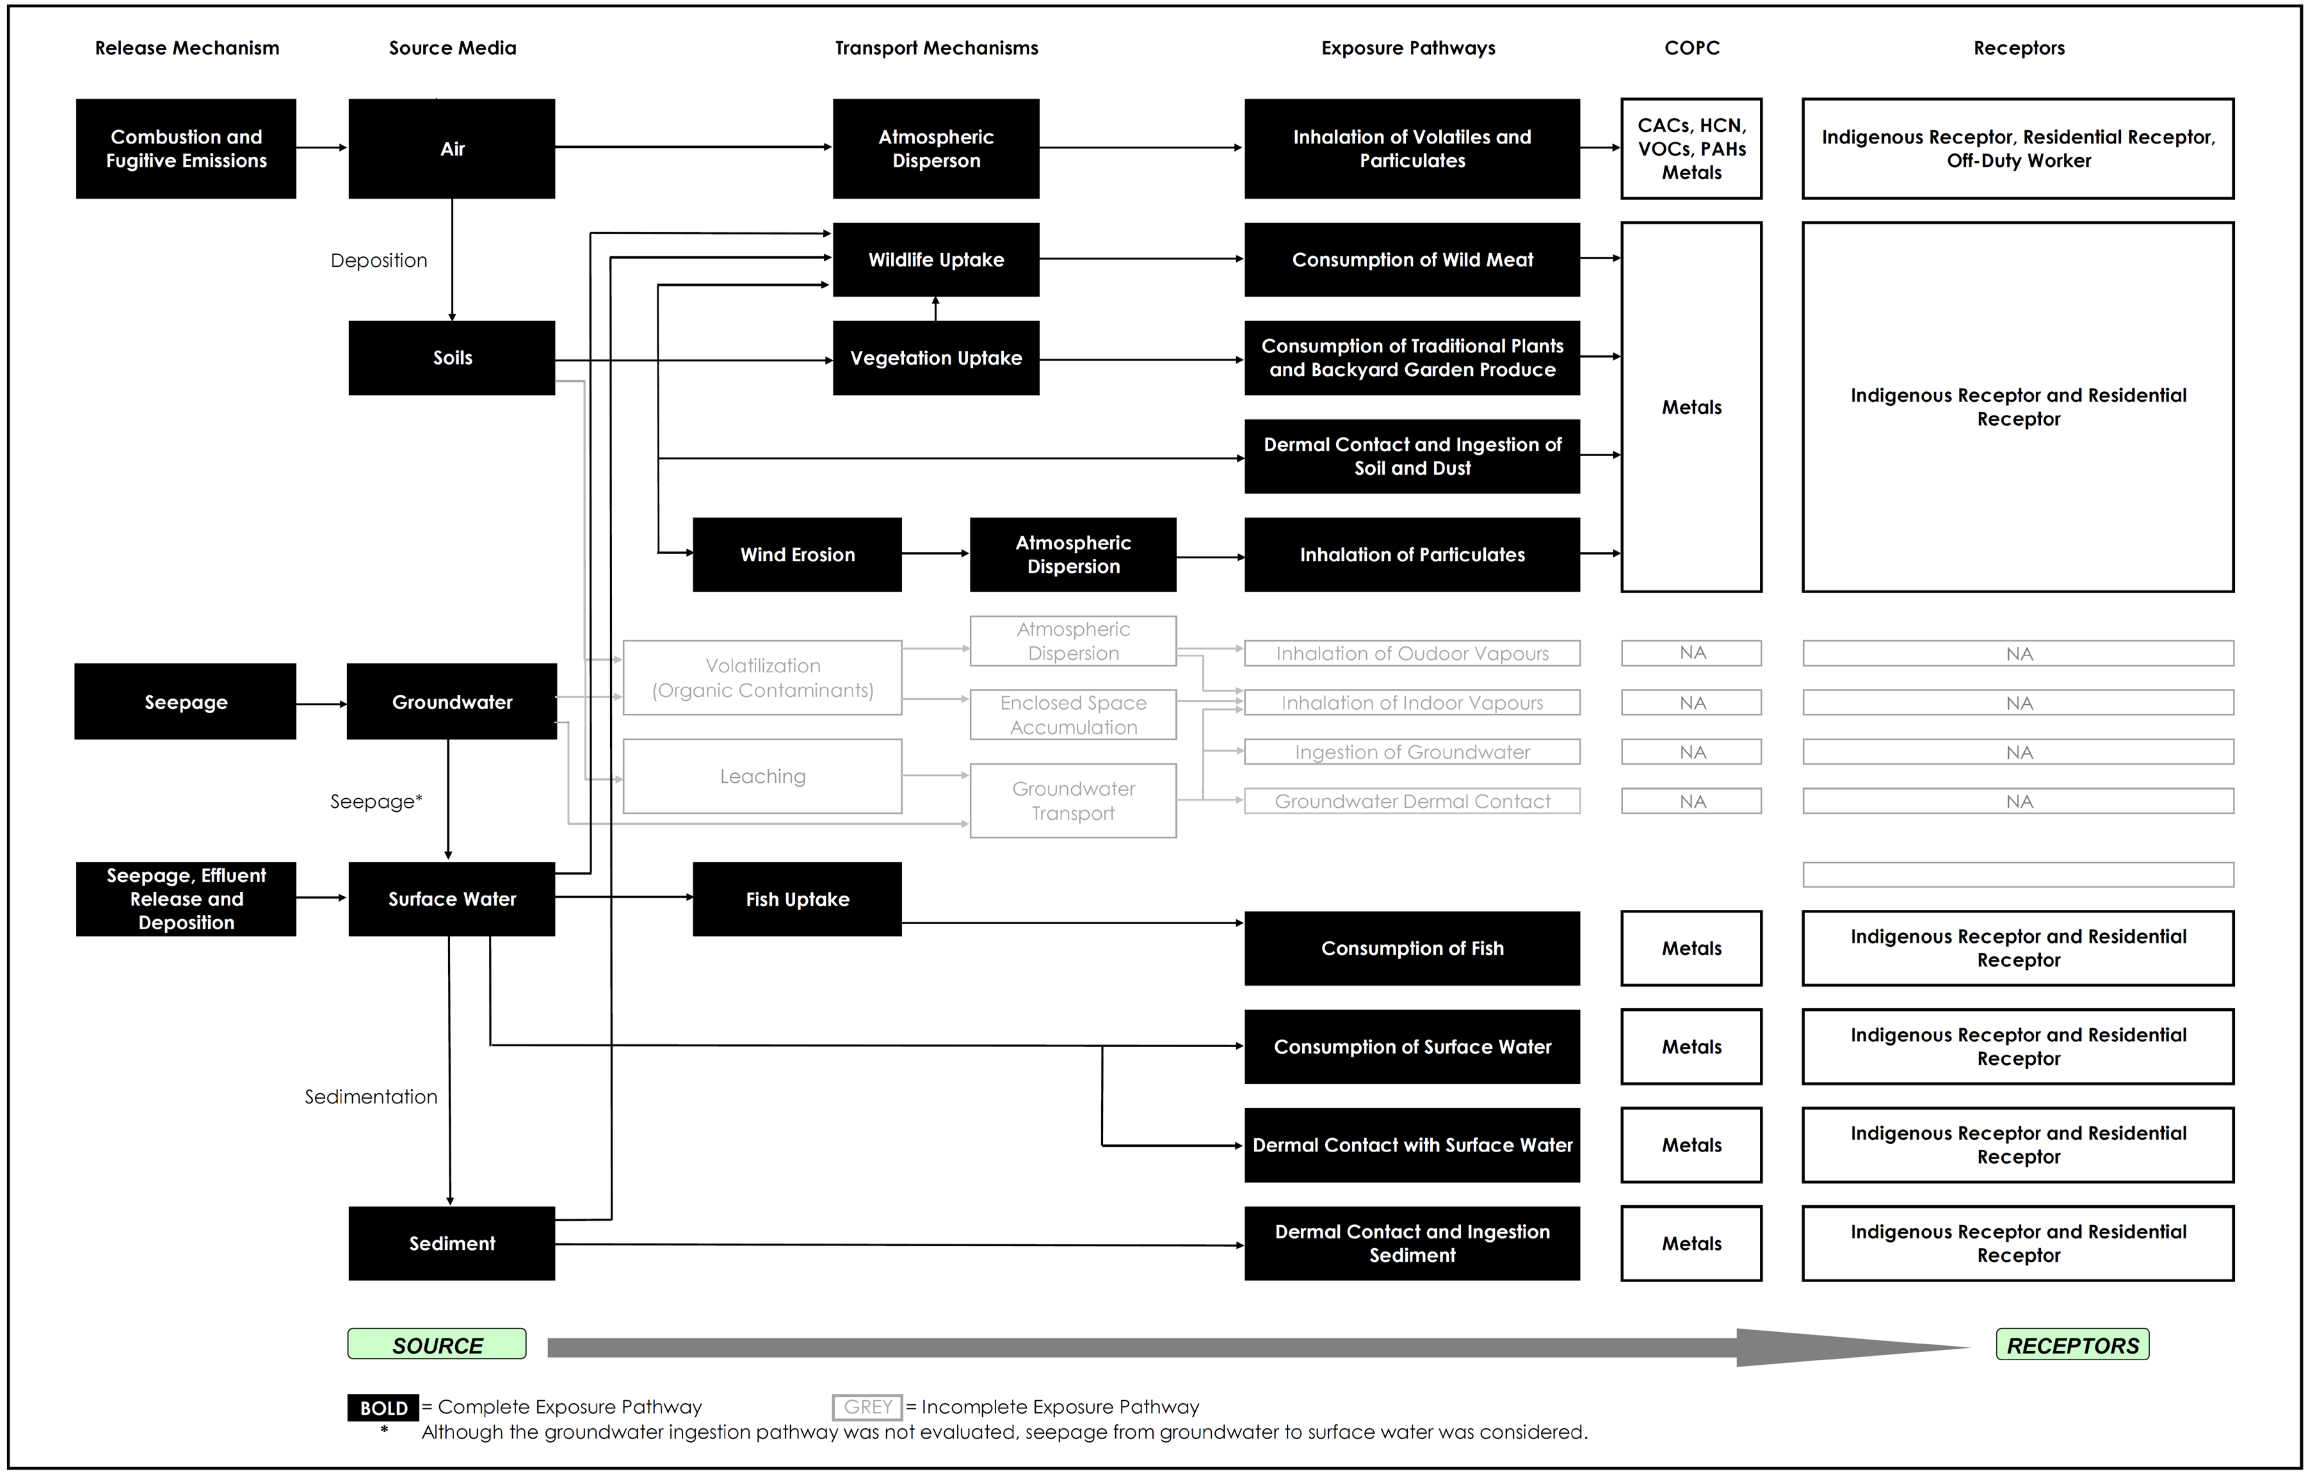
Table 5-4 Rationale for Exposure Pathway Inclusion in the HHRA

Exposure Pathway	Receptor Category	Carried Forward for HHRA	Rationale
Inhalation of COPC from air emissions (Short-term and Long-term)	Indigenous Receptor	Yes	COPC will be released to the air from Project-related activities. Each of the three receptors could inhale COPC released to the air as a result of Project-related activities. For this reason, this exposure pathway was evaluated in this assessment. Both short-term and long-term exposures were assessed.
	Residential Receptor	Yes	
	Off-Duty Workers	Yes	
Incidental ingestion and dermal contact with soil	Indigenous Receptor	Yes	Dust dispersion and deposition from Project-related activities could affect soil quality. Indigenous and Residenital receptors could come in direct contact with soil through ingestion or dermal contact. For this reason, this exposure pathway was evaluated in this assessment. The ground in the work camp will be covered by buildings or aggregate material. Deposited dust would accumulate in the interstitial spaces in the aggregate and would not contribute to incidental soil ingestion or dermal contact for Off-Duty Workers in the camp. For this reason this pathway has not been assessed for Off-Duty Workers.
	Residential Receptor	Yes	
	Off-Duty Workers	No	
Surface Water Ingestion	Indigenous Receptor	No	On occasion, receptors could ingest water directly from the lakes located in their particular region; however, based on the results of engagement, which indicate that people do not obtain drinking water directly from the lakes in either region, these occurrences are expected to be infrequent. The the predicted future concentrations of metals in the lakes in the Gordon region and the MacLellan region are less than the applicable Canadian drinking water guidelines (**Table 5-2**), suggesting that even if the water were used for consumption, health risks related to metal exposures would be negligible. Therefore, the ingestion of surface water pathway by human receptors was not assessed further.
	Residential Receptor	No	
	Off-Duty Workers	No	
Consumption of traditional vegetation	Indigenous Receptor	Yes	Deposition of dust and metals on soils, and subsequent accumulation in vegetation could occur as a result of Project activities. Indigenous receptors and residential receptors could consume traditional vegetation. For this reason, this exposure pathway was evaluated in this assessment. However, Off-Duty Workers would not consume traditional vegetation. For this reason this pathway has not been evaluated to Off-Duty Workers.
	Residential Receptor	Yes	
	Off-Duty Workers	No	
Consumption of garden produce	Indigenous Receptor	Yes	Deposition of dust and metals on soils, and subsequent accumulation in garden produce could occur as a result of Project activities. This could change concentrations in garden produce. Indigenous receptors and Residential receptors could consume garden produce, therefore this pathway was evaluated. However, Off-Duty Workers
	Residential Receptor	Yes	

Table 5-4 Rationale for Exposure Pathway Inclusion in the HHRA

Exposure Pathway	Receptor Category	Carried Forward for HHRA	Rationale
	Off-Duty Workers	No	would not consume garden produce. For this reason this pathway has not been evaluated to Off-Duty Workers.
Consumption of Wild Meat	Indigenous Receptor	Yes	Changes in soil, surface water and vegetation concentrations can result to changes in wild meat concentrations. Indigenous and Residential receptors may consume wild meat. For this reason, this exposure pathway was evaluated for Indigenous and Residential receptors. However, Off-Duty Workers would not consume wilrd meat. For this reason this pathway has not been evaluated for Off-Duty Workers.
	Residential Receptor	Yes	
	Off-Duty Workers	No	
Fish Ingestion	Indigenous Receptor	Yes	Changes in surface water quality due to Project-related activities could result in higher concentrations of COPC in fish tissues. Indigenous receptors and Residential receptors could consume local fish. For this reason, this exposure pathway was evaluated for Indigenous and Residential receptors. However, Off-Duty Workers would not consume fish. For this reason this pathway has not been evaluated to Off-Duty Workers.
	Residential Receptor	Yes	
	Off-Duty Workers	No	
Ingestion and dermal contact with groundwdater	Indigenous Receptor	No	There are no known active groundwater water wells used as a source of drinking water in the Groundwater LAA/RAA. For this reason, this exposure pathway was not evaluated.
	Residential Receptor	No	
	Off-Duty Workers	No	
Incidental ingestion and dermal contact with sediment	Indigenous Receptor	No	Humans could come in direct contact with sediment; however, risks related to sediment contact are considered minor. There are no public beaches or areas of shoreline where high intensity activities occur were identified in the Gordon or MacLellan regions and locations where humans could be exposed to sediment are remote and exposure would be infrequent. With the exception of cobalt from the MacLellan region, vanadium from the Gordon region, and manganese and nickel from the Gordon and MacLellan regions, Baseline Case and Future Case concentrations of metals in sediment are below the applicable soil quality guidelines for protection of human health (Table 5-3). Baseline Case concentrations of the identified metals in sediment exceed the applicable guidelines and the Project-related increases in sediment concentrations from the two regions are predicted to be less than 5%. For this reason, this exposure pathway was not evaluated.
	Residential Receptor	No	
	Off-Duty Workers	No	

Figure 5-1 Conceptual Site Model for the Human Health Risk Assessment



5.2 EXPOSURE ASSESSMENT

The main objective of the exposure assessment is to develop a quantitative estimate of exposure for human receptors to each COPC, based on COPC concentrations in environmental media and receptor characteristics.

Section 4.0 presented the EPCs used in the risk assessment for air, soil, vegetation, surface water, wild meat, fish tissue for the Baseline Case and the Future Case, as well as the Project Alone Case (where applicable). The HHRA used these EPCs to estimate exposure, or dose for the assessment of human health risk. The exposure dose summary tables are provided in Appendix F.

5.2.1 Methods

5.2.2 Calculation of Average Daily Dose

5.2.2.1 Inhalation Exposures

The inhalation TRVs for non-carcinogenic COPC are expressed as chemical concentrations in air (e.g. mg/m^3) rather than as doses on a per body weight basis (mg/kg-day). As a result, potential human health risks associated with inhalation exposures to COPC are characterized by comparing the predicted COPC concentration in air with the corresponding TRVs (Section 5.3.3). Inhalation TRVs are provided for specified exposure durations (e.g. 1-hour, 2-hour, 24-hour, annual average). If the exposure durations anticipated for specific receptors are shorter than the exposure durations assumed in the derivation of the TRVs, it is appropriate to convert the shorter duration exposures that may be experienced by the receptors to an exposure duration that is equivalent to the exposure durations stipulated for the TRV. Therefore, where the exposure durations for the Indigenous, Residential or Off-Duty Worker are anticipated to be shorter than the exposure duration stipulated by the TRVs, COPC concentrations have been adjusted to provide exposure-duration equivalent COPC concentrations for estimating potential inhalation health risks.

As noted in Section 5.1.1.1, Indigenous and Residential receptors are assumed to be present in a given area 24 hours per day on a continuous year-round basis, and no distinction has been made between the time a receptor may spend indoors or outdoors. Therefore, for these receptors, it is not necessary to adjust the predicted COPC concentrations in air prior to comparison with the respective TRVs. The COPC concentrations for the various exposure averaging periods (1-hour, 2-hour, 24-hour, annual average) can be compared directly to the respective TRVs to estimate the potential inhalation health risk for these receptor groups.

Workers employed on the mine-site would be expected to spend a total of 26 weeks/year in camp (based on a 14 days on/14 days off work rotation). For COPC where the exposure benchmarks or TRVs are based on short-term exposure duration (1-hour, 2-hour and 24-hour), concentrations were compared directly to the corresponding CAAQS or TRV without adjustment.

For CACs, the annual exposure benchmarks are based on air quality standards that are considered protective of health (rather than toxicological reference values). By convention, air quality standards for CACs are compared to a statistical interpretation of the chemicals concentrations in air (e.g., annual average CAAQS for $PM_{2.5}$, based on the 3-year average of the annual average of all 1-hour concentrations) and not personal (receptor) exposures. Therefore, exposures to CACs, including annual exposures were not adjusted and were directly comparted to the CAAQS. This approach will over-estimate the exposures that would likely be experienced by workers.

For all other COPC, the annual exposure benchmarks are based on TRVs and the predicted maximum COPC concentrations are adjusted to account for the time the Workers are in the LAA (i.e., 26 weeks/52 weeks per year) to provide annual average exposure estimates that are compared to the TRVs. COPC concentrations were adjusted as shown in Equation 5-1 to represent the effective annual average and lifetime averaged daily exposures that Workers could be expected to experience while in the work camp. The overall adjustment factors based on the exposure duration are provided in Table 5-5. These values have been applied to the predicted maximum COPC concentrations for the annual averaging period to calculate the COPC concentrations (annual average and lifetime daily average) used to characterize potential inhalation health risks for workers in the camp.

For the carcinogenic chemicals, the assessment of potential risk is based on a comparison of the lifetime averaged daily concentration of the chemical in air. Although inhalation exposures to the carcinogenic COPC will only occur over the operation phase of the Project (i.e., 13 years), the predicted Future Case concentrations of carcinogenic COPC in air must be converted to lifetime averaged daily concentration (LADC) so that the predicted lifetime exposures can be properly compared to the carcinogenic inhalation TRV. For inhalation exposures for Workers, LADC (inhalation exposure) in µg/m^3 is calculated as shown in Equation 5-1 using the values of D1, D2, D3 and D4 provided in Table 5-5. For Indigenous Receptors and Residential Receptors who will not be present within the PDA, but are assumed to be present in the LAA on a continuous year-round basis, the LADC is calculated as shown in Table 5-5 based on the assumption that a receptor could be at a given location 24 hours per day 7 days per week 52 weeks per year over the full 13-year operational life of the mine.

Equation 5-1

$$Dose\ \left({}^{\mu g}/_{m^3}\right) = \frac{C_A \times RAF_{Inh} \times D_1 \times D_2 \times D_3 \times D_4}{LE}$$

Where:

Dose	Adjusted chemical concentration (inhalation)	µg/m^3
C_{air}	Chemical concentration in air	µg/m^3
RAF_{Inh}	Relative Absorption Factor (inhalation) (Assumed to be 1 for all COPC)	Unitless
D_1	Hours per day exposed (24 hours)/ 24-hours	Unitless
D_2	Days per week exposed (7days) / 7 days	Unitless
D_3	Weeks per year exposed (26 weeks) / 52 weeks	Unitless
D_4	Total years exposed at the site (13 years- used for carcinogens only)	Years
LE	Life expectancy (80 years) (used for carcinogens only)	Years

Table 5-5 Adjustment Factors for Inhalation Exposures

Exposure Averaging Period	D1			D2			D3			D4	Life Expectancy	Overall Adjustment Factor	
	Hours of exposure	Hours per day	Fraction of Day exposed	Days /week of Exposure	Days/Week	Fraction of Week Exposed	Weeks per year of Exposure	Total Weeks per year	Fraction of Year Exposed	Years of exposure			
	(A)	(B)	(D_1=A/B)	(E)	(F)	(D_2=E/F)	(G)	(H)	(D_3=G/H)	(D_4)	LE	Calculation	Value
Annual Average (Worker)	24	24	1	7	7	1	26	52	0.5	-	-	$D_1 \times D_2 \times D_3$	0.5
Lifetime Averaged (Worker)	24	24	1	7	7	1	26	52	0.5	13	80	$\frac{(D_1 \times D_2 \times D_3 \times D_4)}{LE}$	0.081
Lifetime Averaged (Indigenous and Residential Receptors)	24	24	1	7	7	1	52	52	1	13	80	$\frac{(D_1 \times D_2 \times D_3 \times D_4)}{LE}$	0.16

5.2.2.2 Ingestion and Dermal Contact Exposures

Daily intakes from soil, backyard produce and country foods (e.g., vegetation, fish, wild meat) are determined for each individual COPC. Receptor assumptions for exposure to soil were based on recommendations in Health Canada (2012). Site-specific assumptions include;

- Receptors obtain 10% of the daily fish intake from their region and
- Receptors obtain 10% of their daily intake of vegetables from backyard produce.

Information gathered during Indigenous and community engagement suggests that people are unlikely harvest fish from lakes in either region due to concerns of perceived contamination of the lakes by pervious mining activities in the region. Therefore, the assumption that 10% the fish an individual consumes on a yearly basis is harvested from either the Gordon region (Swede Lake) or the MacLellan region (Cockeram Lake) it considered conservative. The assumption that 10% of vegetable intake comes from backyard produce is consistent with CCME (2006).

Site-specific consumption rates and details on the proportion of each country food consumed were not available. As a result, this HHRA relied upon the recommended consumption quantities in Health Canada (2012) as well as the information provided in Chan et al. (2012) and as presented in Table 5-1.

Daily intakes are calculated in the form of chronic daily intakes (CDIs) (to assess non-carcinogenic endpoints) and lifetime average daily doses (LADDs) (to assess carcinogenic endpoints), using the equations presented below.

Equation 5-2

$$CDI_i = Intake_{nc} \text{ x } EPC_i$$

$$LADD_i = Intake_c \text{ x } EPC_i$$

Where:

CDI_i = chronic daily intake via pathway *i*, mg/kg bw-day (Note: bw means body weight);
$LADD_i$ = lifetime average daily dose via pathway *i*, mg/kg bw-day;
$Intake_{nc}$ = intake rate for medium *i* (e.g., fish) (non-carcinogenic), kg medium/kg bw-day;
$Intake_c$ = intake rate for medium *i* (e.g., fish) (carcinogenic), kg medium/kg bw-day; and
EPC_i = Exposure concentration of chemical in medium *i* (e.g., fish), mg COPC/kg medium.

Similar to the inhalation assessment, for the multi-pathway assessment, EPCs considered representative of the predicted concentrations for a specific media (e.g., soil, vegetation, fish) in a specific region were used to assess health risks for the receptor associated with that particular region. Additional exposure assumptions include the following:

- Receptors obtain 100% of their intake of soil, wild meat and traditional plants and 10% of their fish and vegetables (as backyard produce) from their respective regions.

5.3 TOXICITY ASSESSMENT

Toxicity is the potential for a chemical to produce damage (whether permanent or temporary) to the structure or functioning of the receptor's body. The toxicity of a chemical depends on the amount taken into the body (referred to as the "dose") and the duration of exposure (the length of time the receptor is exposed to the chemical). For each chemical, there is a specific dose and duration of exposure necessary to produce a toxic environmental effect in a given receptor. This is referred to as the "dose-response relationship" of a chemical. The toxic potency of a chemical is dependent on the inherent properties of the chemical itself (its ability to cause a biochemical or physiological response at the site of action within the receptor's body) as well as the ability of the chemical to reach the site of action. This dose-response principle is central to the risk assessment methodology.

5.3.1 Toxicological Reference Values

The toxicity assessment (also known as a hazard assessment) involves the selection of toxicological reference values (TRVs), also referred to as exposure limits, for each COPC. Two general categories of chemicals are commonly recognized by agencies and applied when estimating TRVs for human health (US EPA 1989a). These categories are based on a chemical's mode of action in the body and include "threshold" chemicals (typically used to evaluate non-carcinogenic substances) and "non-threshold" chemicals (typically used for carcinogenic substances).

In the case of threshold chemicals, a threshold level must be exceeded for toxicity to occur. Generally, at low doses the body is able to remove the substances from the body without the substance causing an adverse or toxic effect. As the dose or exposure increases, the body's ability to clear the substances is reduced. When the exposure to a substance exceeds the body's ability to process and excrete the substance, it can cause adverse or toxic effects. The point at which this occurs is called the threshold. The threshold is different for each chemical. The exposure limits developed for each substance reflect the threshold for each chemical. Exposure limits for oral/dermal exposure and inhalation exposures are developed from toxicological studies of human or animal populations and are set so that no adverse effects will result for the established exposure limit. The derivation of a TRV is often based on the identification of a no observable adverse effect level (NOAEL) which is the dose or amount of the chemical that results in no obvious response in the most sensitive test species and test endpoint. The application of uncertainty or safety factors to the NOAEL provides an added level of protection, allowing for derivation of a TRV that is expected to be safe to the general public (including sensitive members of the population) following exposure for a prescribed period of time. Generic nomenclature for TRV for threshold chemicals includes tolerable concentration (TC), which refers to the acceptable concentration of an airborne chemical for which the primary route of exposure is inhalation, and tolerable daily intake (TDI), which refers to the acceptable dose of a chemical and is most commonly expressed in terms of the total intake of the chemical per unit of body weight per day (mg/kg-day).

Non-threshold chemicals (e.g., a carcinogen), work through a non-threshold mechanism. This means that any exposure to a non-threshold chemical is associated with some level of risk. At very low doses, the probability that an adverse effect will occur is extremely small. The probability of an adverse effect occurring increases as the dose increases. Agencies such as Health Canada and the US EPA assume that any level of long-term exposure to carcinogenic chemicals is associated with some “hypothetical cancer risk”. As a result, agencies have typically employed acceptable incremental lifetime cancer risk (ILCR) levels (i.e., levels over and above those that one would expect to be exposed to from background sources other than related to the Project). Generic nomenclature for TRV for non-threshold chemicals includes unit risk (UR), defined as the upper-bound excess lifetime cancer risk estimated to result from continuous exposure to an agent at a unit concentration of 1 mg/L in water, or 1 mg/m^3 in air (US EPA 1989a), and cancer Slope Factor (SF), which is generally defined as the upper-bound increased cancer risk from a lifetime exposure to a substance usually expressed in units of proportion (of a population) affected per mg/kg-day (US EPA 1989a).

5.3.2 Methods

A number of sources were consulted in the selection of TRVs for assessing inhalation and oral exposures to COPC. These sources are provided below along with the TRVs selected for the HHRA.

Order of preference was based on recommendations in Health Canada (2012):

- Health Canada
- US EPA IRIS
- WHO: International Programme on Chemical Safety (INCHEM, WHO 2019)
- RIVM
- ATSDR
- CalEPA
- TCEQ
- MECP or AEP

5.3.3 Inhalation Ambient Air Quality Criteria (CAC)

Non-carcinogenic inhalation TRV for CAC are provided in Table 5-6. Canadian Ambient Air Quality Standards (CAAQS) have been developed for nitrogen dioxide (NO_2) sulphur dioxide (SO_2) and fine particulate matter ($PM_{2.5}$). While CAAQS are not TRVs, ongoing reviews of the CAAQS help confirm they reflect the latest scientific information and are sufficiently stringent to protect human health and the environment (CCME 2014). Therefore, the CAAQS are considered appropriate for the purposes of calculating CRs.

Table 5-6 Non-Carcionogenic Inhalation Toxicological Reference Values for CAC

COPC	Averaging Period	Air Quality Standard (µg/m³)	Health Endpoint	Source
CAC				
SO_2	1-hour	1.7E+02[a]	Respiratory Health Effects	CAAQS (Year 2025) CCME (2017)
	24-hour	1.3E+02	Respiratory Health Effects	AEP (2016)
NOx (As NO_2)	1-hour	7.9E+01[b]	Respiratory Health Effects	CAAQS (Year 2025) CCME(2017)
	Annual	2.3E+01[c]	Respiratory Health Effects	CAAQS (Year 2025) CCME(2017)
$PM_{2.5}$	24-hour	2.7E+01[d]	Health Effects	CAAQS (Year 2020) CCME (2017)
	annual	8.8E+00[e]	Health Effects	CAAQS (Year 2020) CCME (2017)

NOTES:
[a] Based on the 3-year average of the annual 99th percentile of the daily maximum 1-hour average concentrations.
[b] Based on the 3-year average of the annual 98th percentile of the daily maximum 1-hour average concentrations.
[c] The average over a single calendar year of all 1-hour average NO_2 concentrations
[d] Based on the 3 year average of the annual 98th percentile of the daily 24-hour average concentrations.
[e] Based on the 3-year average of the annual average of all 1-hour concentrations.

5.3.4 Inhalation Toxicological Reference Values

The TRV for non-carcinogenic chemicals selected for use in the HHRA are considered protective of the general population, including sensitive subpopulations and life stages including the infant, toddler, child, teen and adult.

5.3.4.1 Inhalation TRV for DPM and HCN

The inhalation TRVs for DPM and HCN are provied in Table 5-7 and Table 5-8.

Table 5-7 Non-Carcionogenic Inhalation Toxicological Reference Values for Diesel Particulate Matter (DPM)

COPC	Averaging Period	TRV (µg/m³)	Health Endpoint	Source
DPM	2-hour	1.0E+01[a]	Respiratory Responses in the General Population	Health Canada (2016c)
	Annual	5E+00[b]	Respiratory Responses in the General Population	Health Canada (2016c)

NOTES:
[a] For non-cancer short-term exposure.
[b] For non-cancer chronic exposure.

Table 5-8 Non-Carcionogenic Inhalation Toxicological Reference Values for Hydrogen Cyanide (HCN)

COPC	Averaging Period	TRV (µg/m³)	Health Endpoint	Source
Hydrogen Cyanide	1-hour	3.4E+02	Central Nervous System	OEHHA (2008)
	Annual	2.5	Thyroid enlargement and altered iodide uptake	US EPA (2010) modified by MECP (2019)

5.3.4.2 Inhalation TRV for VOC

Inhalation TRV for non-carcinogenic and carcinogenic VOCs are provided in Table 5-9 and Table 5-10.

Table 5-9 Non-Carcinogenic Inhalation Toxicological Reference Values for VOC

COPC	Averaging Period	TRV (µg/m³)	Health Endpoint	Source
VOC				
Acetaldehyde	1-hour	1.4E+03	Increased airway responsiveness in asthmatics	Health Canada (2018a)
	24-hour	2.8E+02	Olfactory epithelial degeneration in the nasal cavity	Health Canada (2018a)
	Annual	9E+00	Degeneration of olfactory epithelium	US EPA (1991a)
Acrolein	24-hour	1.1E+01	Eye, nose, and throat irritation and decreased respiratory rate	TCEQ (2015a)
	Annual	2E-02	Nasal Lesions	US EPA (2003a)
Benzene	1-hour	5.8E+02	Depressed peripheral lymphocytes and depressed mitogen-induced blastogenesis of femoral B-lymphocytes	TCEQ (2015b)
	24-hour	3.2E+02	Depressed peripheral lymphocytes and depressed mitogen-induced blastogenesis of femoral B-lymphocytes	TCEQ (2015b)
	Annual	3.0E+01	Decreased lymphocyte count	US EPA (2003b)
1,3-Butadiene	1-hour	3.7E+03	Developmental toxicity; reduction in extra gestational weight gain and in fetal body weight	TCEQ (2008)
	24-hour	9.5E+02	Developmental toxicity; reduction in extra gestational weight gain and in fetal body weight	TCEQ (2015c)
	Annual	2.0E+00	Reproductive- Ovarian atrophy	US EPA (2002)
Ethylbenzene	1-hour	8.6E+04	Ototoxicity	TCEQ (2015d)
	Annual	1.0E+03	Developmental Toxicity- Reduced litter size; increased relative liver, kidney and spleen weights of dams, skeletal variations.	Health Canada (2010b)
Formaldehyde	1-hour	1.2E+02	Eye irritation	Health Canada (2018a)
	24-hour	5.0E+01	Eye and nose irritation	TCEQ (2015e)
	Annual	1.0E+01	Histological changes in the nasal mucosa	ATSDR (1999)
Propionaldehyde	1-hour	1.8E+03	Mild irritation of mucosal surfaces	TCEQ (2015f)
	Annual	8E+00	Atrophy of olfactory epithelium	US EPA (2008)

Table 5-9 Non-Carcinogenic Inhalation Toxicological Reference Values for VOC

COPC	Averaging Period	TRV (µg/m³)	Health Endpoint	Source
Toluene	1-hour	3.7E+04	Reproductive/development; headache, dizziness, sensory irritation	OEHHA (1999a)
	24-hour	2.3E+03	Neurobehavioural test results	Health Canada (2018a)
	Annual	3.8E+03	NOAEL based on exposure of humans for 6h/d	Health Canada (2010b)
2,2,4-Trimethylpentane	1-hour	1.9E+04	Transient neurobehavioral impairments and neurological function impairments	TCEQ (2016)
	Annual	1.8E+03	Free-standing NOAEL due to lack of general systemic effects	TECQ (2016)
Xylenes	1-hour	2.2E+04	Central Nervous System Impairment, respiratory and eye irritation	OEHHA (1999b)
	24-hour	7.3E+02	Health	MOE (2012)
	Annual	1.8E+02	Maternal effects, fetal retardation, increased proportion of fetal mortality and resorbed fetuses	Health Canada (2010b)

Arsenic	1.8E+00	Bladder, lung, liver	Health Canada (2010b)

5.4 RISK CHARACTERIZATION

The final step in the HHRA is risk characterization. The risk characterization compares the estimated exposures to the COPC for each of the receptors with the toxicity reference values to determine if site related exposures exceed the identified limits. Because of the differences in the biological mechanisms of action between non-carcinogenic and carcinogenic chemicals, the potential hazard/risks are determined differently. The characterization of the hazards associated with exposure to non-carcinogenic chemicals and the risks associated with exposure to carcinogenic chemicals (e.g., arsenic) are presented below.

5.4.1 Non-carcinogenic Chemicals

The assessment of human health risks from non-carcinogenic chemicals is conducted using CRs for the inhalation pathway and hazard quotients (HQs) for other pathways. Consistent with Health Canada (2019a), a target CR or HQ of 1.0 is considered applicable for non-carcinogenic chemicals, assuming all potential exposure media and pathways are considered, including background dietary intake. Where an HHRA evaluates only project-related exposures (excluding background estimated daily intake for sources not related to the project, including consumer products, food, air, and water), a target HQ of less than or equal to 0.2 will be deemed negligible to compensate for the exposures not taken into consideration.

The CRs were used to evaluate the health risks from short-term and long-term exposure of all life stages to CACs, non-metal COPC and metal COPC in air. The CRs for CACs were calculated by dividing the appropriate statistical interpretation of the chemical concentrations in air (not adjusted for exposure) by the CAAQS and compared to a CR of 1.0. For other COPC where TRVs for short-term exposures (1-hour, 2-

hour, 24-hour) were available, the CRs were calculated using unadjusted COPC concentrations and the potential health risks were evaluated using a CR benchmark of 1.0. The CRs for annual exposures to other COPC were adjusted based on the time spent in the LAA and were compared to the TRVs. Indigenous and Residential receptors were assumed to spend 100% of their time in the LAA and thus, for these receptors, adjustment of the annual average concentrations to account for time spent away from the LAA was not necessary. However, in estimating the LADC for the Indigenous and Residential receptors, it was necessary to calculate a LADC based on 13 years of mine operation over an 80-year lifetime. Off-Duty Workers would be in the LAA for 26 weeks per year. Therefore, the predicted annual average COPC concentrations were adjusted by a factor of 0.5 for account for the period of the year when these workers would away from the LAA. The LADC for the Off-Duty Workers were also adjusted based on 13 years of mine operation over an 80-year lifetime.

In general, the health effects and risks associated with inhalation exposures are distinct from those associated with oral and dermal exposures and thus, inhalation health risks are assessed independently from oral/dermal exposure risks. For these receptors and exposure durations, where inhalation exposures have been assumed to occur on a continuous basis and Project-related exposures represent the predominant contributor to exposure, a CR benchmark of 1.0 is appropriate for assessing potential risks.

HQs were calculated by dividing the predicted exposure (or dose) by the oral TRV for a specific COPC. People are potentially exposed to chemicals through five main media (i.e., air, water, soil, food, and consumer products). Where an HHRA evaluates only Project-related exposures and excludes background risk from other sources, a target HQ of 0.2 is considered appropriate (Health Canada, 2019a) For this HHRA, the potential non-carcinogenic health risks associated with ingestion, soil, and country food was undertaken, and the health risks associated with each source were compared to the benchmark HQ of 0.2.

As discussed above, if the Future Case risks are less than the target benchmark (CR<1.0 or HQ<0.20), human health risks related to the Project are considered to be negligible. If predicted human health risks, under Baseline Case and/or Future Case conditions are higher than the benchmark, it does not necessarily indicate that an adverse health effect will occur, but rather it triggers a more in-depth review. Review of such CR and HQ values is important since both the exposure estimates and the toxicological criteria are based on a series of conservative assumptions, including multiple predictive models and reasonable "conservative" exposure scenarios. In situations where the CR or HQ approaches or exceeds the established risk acceptability benchmarks, a detailed review of the assumptions is necessary to provide a greater degree of confidence that the assumptions are not unreasonable precautionary or conservative (Alberta Health and Wellness, 2011, Health Canada 2019a).

5.4.2 Carcinogenic Chemicals

Potential health risks associated with inhalation exposures to cancer-causing COPC were expressed as concentration ratios (CR). The CRs were derived by dividing the LADC of the carcinogenic COPC in air by the risk-specific concentration (RsC) associated with a 1 in 100,000 incremental increase in lifetime cancer risk. The RsC is derived from the inhalation unit risk (IUR) (provided in **Section 5.3.3**) as shown below. A CR less than 1.0 indicates that the cancer risks associated with the predicted exposures to the COPC would not exceed the risk acceptability benchmark of 1 in 100,000 established by regulatory agencies such as Health Canada and the CCME.

$$RsC\ \left(\frac{mg}{m^3}\right) = \frac{10^{-5}}{IUR\ \left(\frac{mg}{m^3}\right)^{-1}}$$

Where:

RsC	Risk-specific concentration	mg/m^3
10^{-5}	Target level of risk	Unitless
IUR	Inhalation unit risk	$(mg/m^3)^{-1}$

Potential health risks associated with non-inhalation exposures to cancer-causing COPC were expressed as Incremental Increase in Lifetime Cancer Risks (ILCR) and represent the increased risk of a person in a given population developing cancer over his or her lifetime as a result of the Project. ILCR consider the increase in risk over and above background risk. For cancer-causing COPC evaluated as part of the soil, or food pathway assessment, ILCR estimates resulting from a lifetime of exposure through multiple pathways were calculated by estimating a lifetime average daily dose (LADD) (over an assumed lifetime for a person of 80 years), and multiplying that LADD by the TRV (which is also referred to as the slope factor (SF)) for cancer-causing contaminants in media other than air. Consistent with Health Canada (2019a, 2012), the ILCR was compared to a benchmark of 1 person in a population of 100,000 (i.e. 0.00001, or $1E^{-05}$) predicted to develop cancer as a result of their contaminant exposure from project-related releases. The ILCR does not include consideration of background risk present under Baseline Case, thus only the Future Case ILCRs are reported and these represent the increase in potential cancer risk due to the Project only.

5.4.3 Human Health Risk via Inhalation

The potential changes in inhalation health risks were assessed for exposures to COPC that include CACs, DPM, HCN, VOCs, PAHs and metals. The risks associated with inhalation exposures to non-carcinogenic chemicals (CAC, DPM, HCN, metals and VOC) were evaluated for 1-hour, 2-hour, 24-hour and/or annual exposure times in cases where time-specific inhalation guidelines were available. The risks associated with inhalation of carcinogenic chemicals (metals, VOCs, and PAHs (as $B[a]P_{TPE}$)) were evaluated based on lifetime exposure. It is noted that inhalation risks for the Indigenous receptor and the Residential receptor in a given region are identical as each receptor is assumed to be present in the region 100% of the time.

The human health risks associated with inhalation exposures to COPC were evaluated for the Indigenous Receptor and Residential Receptor in the Gordon and MacLellan regions and for the Off-Duty Worker at the work camp. A full list of receptor locations, with easting and northing locators, is provided in Table E-2 of Appendix E of the Air Quality Technical Modelling Report (Stantec 2020a). The results of the risk characterization are summarized below.

5.4.3.1 Inhalation Risk – CAC

Gordon Region

Non-cancer risks for CACs such as SO_2, NO_2 and $PM_{2.5}$ were calculated for Baseline Case and/or Future Case for the Gordon region, as provided in Table 5-17 to Table 5-19.

With the exception of exposure to 1-hour NO_2, the CRs associated with inhalation exposures for the CACs are below the benchmark of 1.0. A frequency analysis of the inhalation exposures to 1-hour NO_2 is provided below.

The air quality assessment (Stantec 2020a) provided the measured and predicted NO_2 concentrations for the Baseline Case and Future Case of the Project in the Gordon region. The maximum 3-year average 98th percentile of the daily 1-hour maximum NO_2 concentrations was compared to the 1-hour NO_2 CAAQS for 2020 and 2025. The 1-hour NO_2 CAAQS for 2020 and 2025 reflect the findings of the human health risk assessment for NO_2 completed by Health Canada in 2016 (Health Canada 2016b), but incorporate a recognition of the roles that magnitude and frequency of exposure play in determining the potential health risks associated with inhalation exposures to NO_2. Therefore, at receptor locations where 1-hour NO_2 concentrations are predicted to exceed the 1-hour NO_2 2025 CAAQS (79 $\mu g/m^3$), the assessment of potential human health risks should incorporate consideration of the magnitude and frequency of these exceedances. Consideration is also given to the pattern of exceedances (the time of day and time of year when the exceedances are predicted to occur and whether the exceedances occur in isolation or over consecutive 1-hour periods).

The maximum 3-year average 98th percentile of the daily 1-hour maximum NO_2 concentration in the Gordon region exceeds the 2025 CAAQS of 79 $\mu g/m^3$ (maximum CR – 1.21). An exceedance of a CR is not an indication that human health effects will occur. Rather, it is an indication that additional investigation is required to further characterize potential human health risks. The additional evaluation of potential human health risks associated with inhalation exposures to NO_2 considered how often the 1-hour NO_2 concentrations were predicted to exceed the 2025 CAAQS and whether the exceedances occurred individually, or if they occurred over consecutive 1-hour periods. Individual exceedances of the 1-hour NO_2 CAAQS that are separated by periods of time when the 1-hour NO_2 concentrations are below the CAAQS allow for recovery from the respiratory effects associated with the exposure. Respiratory recovery would be delayed in situations where multiple exceedances of the 1-hour NO_2 CAAQS occur in consecutive hours. Prolonged exposures to 1-hour NO_2 concentrations above the CAAQS could result in increased respiratory effects compared to shorter-term exposures. Thus, exceedances of the 1-hour NO_2 that occur in blocks of time may represent a greater potential human health risk than exceedances that occur on an individual (single hours) or a short-term basis (blocks of several hours). The 1-hour NO_2 concentrations were modelled over a 5-year period representing a total of 43,800 1-hour periods (8,760 hours per year x 5 years).

The assessment of potential human health risks associated with inhalation exposures to NO_2 considered 1-hour and annual average NO_2 concentrations at 45 special receptor locations in the Gordon region. At each of the 45 receptor locations, predicted annual average NO_2 concentrations (including background NO_2) were below the 2025 annual average NO_2 CAAQS. At 42 of these receptor locations, 1-hour NO_2

concentrations were below the 2025 1-hour NO_2 CAAQS (79 µg/m^3). At three special receptor locations, (Map 9 Appendix A) Potential Indigenous Receptor 24, Potential Indigenous Receptor 25 and Potential Indigenous Receptor 27 (all three locations fall within Trapping 22 and Travel 25 identified in the Marcel Colomb First Nation TLRU Study (Stantec 2018), the maximum predicted 1-hour NO_2 concentration exceeded the 2025 1-hour NO_2 CAAQS.

The air quality assessment (Stantec 2020a) modelled 1-hour NO_2 concentrations over a 5-year period (43,800 1-hour NO_2 results per special receptor location). In the Gordon region, the maximum number of exceedances of the 2025 1-hour NO_2 CAAQS over the 5-year modelling period are predicted to occur at the Potential Indigenous Receptor 27, located north of the Gordon PDA (Map 9 Appendix A). At this location, the 1-hour NO_2 concentrations were predicted to exceed the 1-hour NO_2 CAAQS (79 µg/m^3) 170 times over the 5-year modelling period. This represents 0.38% of the time. Exceedances occur predominantly as single events separated by prolonged periods where the 1-hour NO_2 concentrations are below the 2025 1-hour NO_2 CAAQS. There are three instances (April 12 in year 1, May 14 in year 4 and December 14 in year 3) where the exceedances are predicted to occur over 5 consecutive hours. However, the maximum 1-hour NO_2 concentration predicted during these periods is 97 µg/m^3 (May 14 year 4), which is below the 2020 1-hour NO_2 CAAQS. In addition, the 170 exceedances over the 5-year modelling period happen during the colder months (November through May) and between the hours of 20:00 and 6:00 the following morning. Within this period, there is no fixed pattern to when individual exceedances happen. Information provided from Traditional Land and Resources Use studies and in the Manitoba Métis Traditional Knowledge, Land Use, and Occupancy Study for the Lynn Lake Gold Mine Project (SVS 2020), do not identify habitations in the vicinity of the Potential Indigenous Receptor 27, or the other two special receptor locations where exceedances of the 1-hour NO_2 2025 CAAQS, are predicted to occur. In the absence of habitation near these special receptor locations, it is less likely that people would be present in these areas at the time of day when then these exceedances are predicted to occur, than if the exceedances were to occur during daylight hours. In addition, the maximum 1-hour NO_2 concentrations for the modelled five years for each of these three special receptor locations are below the Health Canada short-term Residential Indoor Air Quality Guideline (RIAQG) for NO_2 of 170 µg/m^3 (Health Canada 2018b), and the predicted annual average NO_2 concentrations are below the 2025 annual average NO_2 CAAQS. Predicted annual average NO_2 concentrations at the remaining 44 special receptor locations within the Gordon region are also below the annual average CAAQS.

Based on the results it is reasonable to conclude that occasional exceedances of the 2025 1-hour NO_2 CAAQS represent a negligible human health risk for people who may be in the area.

MacLellan Region

Non-cancer risks for CACs such as SO_2, NO_2 and $PM_{2.5}$ were calculated for Baseline Case and/or Future Case for the Maclellan region, as provided in Table 5-20 to Table 5-22.

With the exception of exposure to 1-hour NO_2, the CRs associated with inhalation exposures for the non-carcinogenic CACs in the MacLellan region are below the benchmark of 1.0. A frequency analysis of the inhalation exposures to 1-hour NO_2 concentrations is provided below.

The air quality assessment provided the measured and predicted NO_2 concentrations for the Baseline Case and Future Case of the Project in the MacLellan region (Stantec 2020a). The assessment of potential human health risk considered 1-hour and annual average NO_2 concentrations at 114 special receptor locations in the Maclellan region. At each of the 114 receptor locations predicted annual average NO_2 concentrations (including background NO_2) were below the 2025 annual average NO_2 CAAQS. At four special receptor locations (Map 9 Appendix A), Potential Indigenous Receptor 36 (north of the MacLellan PDA), Potential Indigenous Receptor 37, Potential Indigenous Receptor 38 (both located southwest of the MacLellan PDA) and Waste Disposal Site 1 (located southeast of the MacLellan PDA), the maximum predicted 1-hour NO_2 concentration exceeded the 2025 1-hour NO_2 CAAQS. As noted above in the discussion for the Gordon region, at receptor locations where 1-hour NO_2 concentrations are predicted to exceed the 1-hour NO_2 2025 CAAQS (79 µg/m³), consideration is given to the magnitude, frequency and the patterns of 1-Hour NO_2 exceedances in the evaluation of potential human health risks.

The air quality assessment (Stantec 2020a) modelled 1-hour NO_2 concentrations over a 5-year period (43,800 1-hour NO_2 results per special receptor location). The maximum number of exceedances of the 2025 1-hour NO_2 CAAQS over the 5-year modelling period, are predicted to occur at the Waste Disposal Site 1 special receptor, located southeast of the MacLellan PDA (167 over the 5-year modelling period). However, of the four special receptor locations within the MacLellan region where 1-hour NO_2 exceedances were predicted to occur, the Waste Disposal Site 1 location is unlikely to represent a location people would be expected to frequent. The three remaining special receptor locations where 1-hour NO_2 exceedances are predicted to occur represent locations that people could reasonably be expected to frequent (Map 9

Appendix A). Of these three locations, the highest number of exceedances of the 1-hour NO_2 2025 CAAQS are predicted to occur at Potential Indigenous Receptor 37 (163 exceedances over the 43,800 hours modelled over the 5-year modelling period). This represents 0.37% of the time. Therefore, the assessment of potential human health risks has focused on the Potential Indigenous Receptor 37 special receptor location to represent the reasonable worst-case exposure. At Potential Indigenous Receptor 37, exceedances occur predominantly as single events of one or two hours, separated by prolonged periods where the 1-hour NO_2 concentrations are below the 2025 1-hour NO_2 CAAQS. There is one instance (March 24 in year 2) where exceedances of the 2025 1-hour NO_2 CAAQS are predicted to occur over 7 consecutive hours. Within this 7-hour period, there are 2 hours where the 1-hour NO_2 concentrations are predicted to exceed the 2020 1-hour NO_2 CAAQS of 113 μg/m^3 (140 μg/m^3 and 132 μg/m^3). The predicted 1-hour NO_2 concentrations in the remaining 5 hours of this 7-hour period are below 113 μg/m^3. The 1-hour NO_2 concentrations in this 7-hour period are below the Health Canada short-term RIAQG of 170 μg/m^3 (Health Canada, 2018b). There is one instance where exceedances are predicted to occur over a 5-hour period (Jan 5 in year 1) and three instances where exceedances are predicted to occur over a 4-hour period (December 12 in year 1, February 16 in year 2 and March 15 in year 3). In these periods, the maximum predicted 1-hour NO_2 concentrations were above the 2025 1-hour NO_2 CAAQS but below the 2020 1-hour NO_2 CAAQS, and the maximum concentrations were below the Health Canada short-term RIAQG (Health Canada, 2018b). In addition, the predicted exceedances occur between 20:00 and 6:00 the following morning. Within this period, there is no fixed pattern to when individual exceedances happen. No habitations have been identified in the area of Potential Indigenous Receptor 37 (SVS 2020). In the absence of habitation near these special receptor locations, it is less likely that people would be present in these areas at the time of day when then these exceedances are predicted to occur, than if the exceedances were to occur during daylight hours. In addition, the predicted annual average NO_2 concentrations were below the 2025 annual average NO_2 CAAQS of 23 ug/m^3.

Based on the results, it is reasonable to conclude that occasional exceedances of the 2025 1-hour NO_2 CAAQS represent a negligible human health risk for people who may be in the area. As noted above, the CRs for the other non-carcinogenic COPC are below 1.0. Therefore, Project related health risks associated with inhalation exposures to the non-carcinogenic CACs are negligible.

Work Camp

Non-cancer risks for CACs (SO_2, NO_2 and $PM_{2.5}$) were calculated for Baseline Case and/or Future Case for the Off-Duty Worker at the work camp, as provided in Table 5-23 to Table 5-25.

With the exception of 1-hour exposure to NO_2, the CRs associated with inhalation exposures of CACs for the Off-Duty Worker do not exceed the benchmark of 1.0. A frequency analysis of the inhalation exposures to 1-hour NO_2 concentrations is provided below.

The 98^{th} percentile of the 1-hour daily maximum NO_2 concentration exceeded the 2025 CAAQS of 79 µg/m^3 (maximum CR of 1.66). The 1-hour NO_2 concentrations were modelled over a 5-year period. Over this 5-year period 1-hour NO_2 concentrations were predicted to exceed the 2025 CAAQS 695 times (1.6% of the time). In general, the predicted exceedances do not occur in blocks of more than 3 consecutive hours, and these are separated by periods where the 1-hour NO_2 concentrations are below the 2020 1-hour NO_2 CAAQS. Exceedances of the 1-hour NO_2 CAAQS could result in increases in respiratory responses such as increased respiratory tract resistance in sensitive members of the workforce (asthmatics). Individual exceedances of the 1-hour NO_2 CAAQS that are separated by periods of time when the 1-hour NO_2 concentrations are below the CAAQS allow for recovery from the respiratory effects associated with the exposure. Respiratory recovery would be delayed in situations where multiple exceedances of the 1-hour NO_2 CAAQS occur in consecutive hours. Prolonged exposures to 1-hour NO_2 concentrations above the CAAQS could result in increased respiratory effects compared to shorter-term exposures. Thus, exceedances of the 1-hour NO_2 that occur in blocks of time may represent a greater potential human health risk than exceedances that occur on an individual (single hours) or a short-term basis (blocks of several hours).

Exceedances of the 1-hour NO_2 CAAQS that occur over more than 3 hours range in duration from 4 hours (80 times) to 11 hours (2 times) and account for a total of 276 hours over the 43,800 hours of the 5-year modelling period. During these periods, particularly sensitive members of the workforce (those with asthma) who are directly exposed to 1-hour NO_2 concentrations above the CAAQS, may experience respiratory effects such as shortness of breath, that would be expected to subside as NO_2 concentrations decline.

The predicted 1-hour NO_2 exceedances usually occur in winter months (December–March). These exceedances generally happen overnight, occurring sometime between 19:00 and 6:00 the following morning. Within this period, there is no fixed pattern to when individual exceedances happen. In addition, in the winter months, between 19:00 and 6:00 workers would generally be expected to spend off-duty time indoors, and thus would not be expected to experience prolonged exposures to NO_2 concentrations that exceed the 1-hour CAAQS.

Considering the results of the assessment of potential health risks associated with inhalation exposures to NO_2, it is reasonable to conclude that inhalation exposure to NO_2 represents a negligible human health risk for Off-Duty Workers housed at the work camp.

5.4.3.2 Inhalation Risk – DPM

Gordon Region

Non-cancer risks for DPM inhalation exposures to Residential Receptors and Indigenous Receptors were calculated for Future Case DPM concentrations at the Gordon region, as provided in Table 5-26 and Table 5-27. The CRs associated with inhalation exposures to 2-hour concentrations of DPM and annual average concentrations of DPM do not exceed the benchmark of 1.0.

Work Camp

Non-cancer risks for DPM inhalation of 2-hour and annual average exposures to Off-Duty Worker Receptor at the work camp were calculated for Future Case, as provided in Table 5-30 and Table 5-31. The CRs associated with 2-hour DPM exposures exceeded the benchmark of 1.0, whereas the CRs associated with annual average exposures was below the benchmark of 1.0. Frequency analysis of inhalation exposures to 2-hour DPM concentrations is provided below.

The DPM concentrations are predicted to exceed the 2-hour air quality standard of 10 µg/m^3 on two occasions (10.4 µg/m^3 and 11.5 µg/m^3). DPM concentrations were modelled over a 5-year period representing a total of 21,900 2-hour periods. Thus, 2-hour DPM concentrations are predicted to exceed the air quality standard 0.009% of the time. The 2-hour DPM air quality standard is based on a lowest observable adverse effect level (LOAEL) of 100 µg/m^3 from studies where increased respiratory resistance was reported in study groups that included subjects that were mildly asthmatic (Health Canada, 2016c). Health Canada applied an uncertainty factor of 10 to the LOAEL to derive the 2-hour exposure limit of 10 µg/m^3 noting that the reported effects were considered mild and reversible (Health Canada 2016c). The predicted 2-hour DPM concentrations in the hours preceding and following the exceedances were below the 2-hour DPM.

Thus, given that the predicted exceedances of the short-term (2-hour) exposure limit are limited (i.e., two occurrences slightly above threshold) and that the health effects associated the 2-hour limit are based on mild and reversible effects in sensitive members of the population (asthmatics), and the maximum predicted annual average exposure for an Off-Duty Worker is below the annual average exposure limit, it is reasonable to conclude that for Off-Duty Workers, short-term and long-term inhalation exposures to DPM represent a negligible human health risk.

5.4.3.3 Inhalation Risk – Hydrogen Cyanide

As provided in Table 5-32 to Table 5-37, CRs based on non-carcinogenic effects were below the target benchmark of 1.0 for the modelled receptor locations and exposure durations (1-hour, and annual). Therefore, inhalation exposures to HCN would present a negligible non-cancer human health risk for receptors located at Gordon and MacLellan Study areas and for Off-Duty Workers in the work camp.

Gordon Region

Non-cancer risks for HCN inhalation exposures to Residential Receptors and Indigenous Receptors were calculated for Future Case HCN concentrations at the Gordon region, as provided in Table 5-32 and Table 5-33. The CRs associated with inhalation exposures to 1-hour, and annual average concentrations of HCN were below the benchmark of 1.0.

5.4.3.4 Inhalation Risk – VOCs

Inhalation risks for non-carcinogenic and carcinogenic VOCs were calculated by comparing the maximum predicted concentrations in air for 1-hour, 24-hour, annual average and lifetime averaged daily concentrations with applicable non-carcinogenic and carcinogenic TRV provided in Section 5.3.3.

As presented in Table 5-38 to Table 5-49, CRs based on non-carcinogenic and carcinogenic effects were below the target benchmark of 1.0 for Gordon region, MacLellan region and the work camp for the relevant exposure durations (1-hour, 24-hour, annual and lifetime averaged daily).

Gordon Region

Non-cancer risks for VOC inhalation exposures to Residential Receptors and Indigenous Receptors were calculated for Future Case VOC concentrations at the Gordon region, as provided in Table 5-38 to Table 5-40. The CRs associated with inhalation exposures to 1-hour, 24-hour and annual average concentrations were below the benchmark of 1.0.

The CRs associated with lifetime averaged daily exposures to carcinogenic VOCs were below 1.0, as provided in Table 5-41.

5.4.3.6 Inhalation Risk – Metals

Inhalation risks for non-carcinogenic and carcinogenic metals were calculated by comparing the maximum predicted concentrations in air for annual average and lifetime averaged daily concentrations with applicable non-carcinogenic and carcinogenic TRVs provided in Section 5.3.3. Concentrations of antimony, barium and strontium are not expected to be emitted to the air by the Project and therefore were not modelled.

As presented in Table 5-56 to Table 5-61, CRs based on non-carcinogenic and carcinogenic risks were below the target benchmark of 1.0 for Gordon region, MacLellan region and the work camp, the relevant exposure durations (annual and lifetime average daily).

Gordon Region

Non-cancer risks for metal particulate inhalation exposures to Residential Receptors and Indigenous Receptors were calculated for Future Case metal concentrations at the Gordon region, as provided in Table 5-56. The CRs associated with inhalation exposures to annual average concentrations were below 1.0.

The CRs associated with lifetime averaged daily exposures to carcinogenic metals were below 1.0, as provided in Table 5-57.

NOTE:
[a] Adjusted EPC based Lifetime Averaged Adjusmment for Off-Duty Workers of 0.081 (Table 5-5)

5.4.4 Human Health Risk via Direct Soil Contact

As noted in Section 4.2 dust deposition predictions were used to estimate potential changes to soil quality. It was assumed that the metal that was deposited to the soil remains in the top 2 cm of the soil and there is no loss throughout the typical human lifetime (i.e., 80 years). Human receptors (i.e., Indigenous Receptor and Residential Receptor) may be exposed to metal COPC within the Gordon region and MacLellan region through incidental ingestion of soil and dermal contact with these soils (i.e., soil contact). Off-Duty Workers are only evaluated for inhalation exposures, as ingestion exposures are assumed to be comparable to those of the general population because this receptor will not consume country foods, backyard foods or untreated water from the LAA. The following assumptions were used to estimate changes in metal concentrations in soil:

- Human receptors were assumed to spend 100% of their time within their particular region.
- Human receptors were assumed to be exposed to the maximum concentration of each COPC predicted in their region (i.e., Gordon region and MacLellan region).
- The combined dust deposition estimates for the Gordon site and the MacLellan site provided by the air quality modelling were assumed to represent the dust and metal deposition rate over the 5-year operational life of the Gordon site and the 13-year operational life of the MacLellan site. The 95% UCLM deposition rate for locations within a given region was used as the deposition rate across the entire region. This approach provides reasonable upper-bound estimates of increases in metal concentrations in soil and therefore the potential exposure to COPC in soil.

As presented in Table 5-62 to Table 5-69, HQs for soil contact were below the target benchmark of 0.2. Therefore, metal concentrations in soil represents a negligible human health risk.

Health risks associated with the metal COPC that are considered carcinogens (e.g.., arsenic) were also assessed at each of the selected deposition receptor locations to evaluate the soil exposure pathway for the two types of human receptors. The ILCRs based on the Project Alone Case are provided in Table 5-70 to Table 5-73. ILCRs for the soil exposure pathway for the two types of human receptors were below the target benchmark of 1.0E-05, indicating that Project-related increase in metal concentrations in soil represents a negligible human health risk.

5.4.5 Human Health Risks via Ingestion of Food

The HQs for the consumption of foods (i.e., fish, wild meat, traditional plant and garden produce) were estimated for the Indigenous Receptors and Residential Receptors in the Gordon region and MacLellan region. Indigenous Receptors are assumed to consume higher levels of country foods, harvested from within their region, compared to the Residential Receptors. The Indigenous Receptors and Residential Receptors were assumed to consume fish, wild meat, traditional plants (i.e., berries and tea) and garden produce from the LAA. As noted in Section 5.4.4, ingestion exposure pathways are not complete for Off-Duty Workers. It is recognized that differences exist in the types and amounts of country foods consumed by individuals. The species and tissues chosen for inclusion in the assessment are representative of the most commonly consumed by receptor groups (Indigenous, Métis, public). Although not all species listed by Indigenous and Métis groups could be included in the assessment, the species selected were chosen as being the most abundant and likely to be the most commonly consumed, thereby providing a reasonable upper bound estimate of potential exposure for the receptor groups considered.

5.4.5.1 Non-Carcinogenic Risks for Ingestion of Food

A summary of HQs for food consumption for the Indigenous Receptors and the Residential Receptors are provided in Table 5-74 to Table 5-81.

Gordon Region

Toddler Indigenous Receptor

HQ for manganese in traditional plants, methylmercury in fish and thallium in wild meat, traditional plants and garden produce exceeded the target benchmark of 0.2 under both Baseline Case and Future Case (Table 5-74). HQs for the remaining COPC were below the target benchmark of 0.2 under both Baseline and Future Case.

The changes in HQ between Baseline Case and Future Case for manganese, methylmercury and thallium were less than the benchmark of 0.2 indicating Project-related health risks are negligible.

Adult Indigenous Receptor

HQ for manganese in traditional plants, methylmercury in fish and thallium in wild meat and traditional plants exceeded the target benchmark of 0.2 under both Baseline Case and Future Case (Table 5-75). HQs for the remaining COPC were below the target benchmark of 0.2 under both Baseline and Future Case.

The changes in HQ between Baseline Case and Future Case for manganese, methylmercury and thallium were less than the benchmark of 0.2 indicating Project-related health risks are negligible.

Toddler Residential Receptor

HQ for manganese in traditional plants and thallium in wild meat, traditional plants and garden produce exceeded the target benchmark of 0.2 under both Baseline Case and Future Case (Table 5-76). HQs for the remaining COPC were below the target benchmark of 0.2 under both Baseline and Future Case.

The changes in HQ between Baseline Case and Future Case for manganese and thallium were less than the benchmark of 0.2 indicating a negligible health risk.

Adult Residential Receptor

HQ for thallium in wild meat exceeded the target benchmark of 0.2 under both Baseline Case and Future Case (Table 5-77). HQs for the remaining COPC were below the target benchmark of 0.2 under both Baseline and Future Case.

The changes in HQ between Baseline Case and Future Case for thallium were less than the benchmark of 0.2 indicating a negligible health risk.

MacLellan Region

Toddler Indigenous Receptor

HQ for manganese in traditional plants, methylmercury in fish and thallium in wild meat, traditional plants and garden produce exceeded the target benchmark of 0.2 under both Baseline Case and Future Case (Table 5-78). HQs for the remaining COPC were below the target benchmark of 0.2 under both Baseline and Future Case.

The changes in HQ between Baseline Case and Future Case for manganese, methylmercury and thallium were less than the benchmark of 0.2 indicating Project-related health risks are negligible.

Adult Indigenous Receptor

HQ for manganese in traditional plants and thallium in wild meat and traditional plants exceeded the target benchmark of 0.2 under both Baseline Case and Future Case (Table 5-79). HQs for the remaining COPC were below the target benchmark of 0.2 under both Baseline and Future Case.

The changes in HQ between Baseline Case and Future Case for manganese and thallium were less than the benchmark of 0.2 indicating Project-related health risks are negligible.

Toddler Residential Receptor

HQ for manganese in traditional plants and thallium in wild meat, traditional plants and garden produce exceeded the target benchmark of 0.2 under both Baseline Case and Future Case (Table 5-80). HQs for the remaining COPC were below the target benchmark of 0.2 under both Baseline and Future Case.

The changes in HQ between Baseline Case and Future Case for manganese and thallium were less than the benchmark of 0.2 indicating a negligible health risk.

Adult Residential Receptor

HQ for thallium in wild meat exceeded the target benchmark of 0.2 under both Baseline Case and Future Case (Table 5-81). HQs for the remaining COPC were below the target benchmark of 0.2 under both Baseline and Future Case.

The changes in HQ between Baseline Case and Future Case for thallium were less than the benchmark of 0.2 indicating a negligible health risk.

5.4.5.2 Carcinogenic Risks for Ingestion of Food

A summary of ILCRs for exposure to arsenic in country food for the lifetime Indigenous Receptor and lifetime Residential Receptor is provided in Table 5-82 to Table 5-85. ILCRs for the food exposure pathway for the lifetime receptors in both human receptors were below the target benchmark of 1.0E-05, indicating that Project-related increase in metal concentrations in food represents a negligible human health risk.

5.4.6 Human Health Risks via Total Ingestion Risks

A summary of HQs for total ingestion for the Indigenous Receptors and the Residential Receptors are provided in Table 5-86 to Table 5-93.

5.4.6.1 Gordon Region

Toddler Indigenous Receptor

The HQ for total ingestion of manganese, methylmercury and thallium exceeded the target benchmark of 0.2 under both Baseline Case and Future Case Table 5-86. HQs for the remaining COPC were below the target benchmark of 0.2 under both Baseline and Future Case.

The changes in HQ between Baseline Case and Future Case for manganese, methylmercury and thallium were 0.3% or less and less than the benchmark of 0.2 indicating Project-related health risks are negligible.

Adult Indigenous Receptor

The HQ for total ingestion of manganese, methylmercury and thallium exceeded the target benchmark of 0.2 under both Baseline Case and Future Case Table 5-87. HQs for the remaining COPC were below the target benchmark of 0.2 under both Baseline and Future Case.

The changes in HQ between Baseline Case and Future Case for manganese, methylmercury and thallium were 0.3% or less and less than the benchmark of 0.2 indicating Project-related health risks are negligible.

Toddler Residential Receptor

The HQ for total ingestion for manganese and thallium exceeded the target benchmark of 0.2 under both Baseline Case and Future Case Table 5-88. HQs for the remaining COPC were below the target benchmark of 0.2 under both Baseline and Future Case.

The changes in HQ between Baseline Case and Future Case for manganese and thallium were 0.3% or less and less than the benchmark of 0.2 indicating Project-related health risks are negligible.

Adult Residential Receptor

The HQ for total ingestion of thallium exceeded the target benchmark of 0.2 under both Baseline Case and Future Case Table 5-89. HQs for the remaining COPC were below the target benchmark of 0.2 under both Baseline and Future Case.

The changes in HQ between Baseline Case and Future Case for thallium was only 0.3% and also less than the benchmark of 0.2 indicating Project-related health risks are negligible.

5.4.6.2 MacLellan Region

Toddler Indigenous Receptor

The HQ for total ingestion of manganese, methylmercury, nickel and thallium exceeded the target benchmark of 0.2 under both Baseline Case and Future Case Table 5-90. HQs for the remaining COPC were below the target benchmark of 0.2 under both Baseline and Future Case.

The changes in HQ between Baseline Case and Future Case for manganese, methylmercury, nickel and thallium were 3% or less and were also less than the benchmark of 0.2 indicating Project-related health risks are negligible.

Adult Indigenous Receptor

The HQ for total ingestion of manganese and thallium exceeded the target benchmark of 0.2 under both Baseline Case and Future Case Table 5-91. HQs for the remaining COPC were below the target benchmark of 0.2 under both Baseline and Future Case.

The changes in HQ between Baseline Case and Future Case for manganese and thallium were 2% or less and were also less than the benchmark of 0.2 indicating Project-related health risks are negligible.

Toddler Residential Receptor

The HQ for total ingestion of manganese and thallium exceeded the target benchmark of 0.2 under both Baseline Case and Future Case (Table 5-92). HQs for the remaining COPC were below the target benchmark of 0.2 under both Baseline and Future Case.

The changes in HQ between Baseline Case and Future Case for manganese and thallium were 2% or less and were also less than the benchmark of 0.2 indicating Project-related health risks are negligible .

Adult Residential Receptor

The HQ for total ingestion of thallium exceeded the target benchmark of 0.2 under both Baseline Case and Future Case Table 5-93. HQs for the remaining COPC were below the target benchmark of 0.2 under both Baseline and Future Case.

The changes in HQ between Baseline Case and Future Case for thallium was only 3% and was also less than the benchmark of 0.2 indicating Project-related health risks are negligible.

The ILCRs for total ingestion for the Indigenous Receptor and the Residential Receptor are provided in Table 5-94Error! Reference source not found. to Table 5-97 . In each case the risk for the Project Alone Case is below the benchmark of 1.0E-05. Therefore Project-related carcinogenic health risks for total ingestion are considered negligible.

5.4.7 Summary

A summary of non-carcinogenic risk estimates for each receptor in excess of the applicable benchmark, as well as a discussion of why potential unacceptable health risks are not expected is provided in Table 5-98 to Table 5-109. Overall, the increase in health risks for each receptor as a result of the Project are considered negligible.

There were no carcinogenic risk estimates for inhalation that exceeded the applicable benchmark. Arsenic is the only COPC that is considered carcinogenic via ingestion. In each case the ILCR based on Project Alone was below the benchmark of 1.0E-05. Overall, the increase in carcinogenic health risks for each receptor as a result of the Project are considered negligible.

Table 5-98 Non-carcinogenic Human Health Risk that Exceeded the Applicable Benchmark – Inhalation- Residential Receptor and Indigenous Receptor (Gordon Region)

COPC	Period	CR		Discussion
		Baseline Case	Future Case	
NO_2	1-hour	9.5E-02	**1.2E+00**	The frequency analysis (Section 5.4.3) demonstrated that the yearly frequency of exceedance is low enough that potential health risks are negligible

5.5 UNCERTAINTY ANALYSIS

This HHRA was conducted according to accepted risk assessment methodologies and follows guidance published and endorsed by Health Canada. This approach is consistent with previous projects that have been reviewed by the Impact Assessment Agency of Canada. Risk estimates were refined through the inclusion of baseline data from multiple types of environmental media (i.e., air, soil, water, and biota), accepted modelling techniques for the prediction of Future Case concentrations, information about likely human receptors and exposure pathways collected through surveys and public meetings, and professional judgement. HHRAs have inherent uncertainty related to the assumptions applied in the risk calculations. This uncertainty is often the result of conservative assumptions aimed at overestimating health risks. Although many factors contribute to a risk estimate, results are generally sensitive to only a few of these factors, which are described below.

5.5.1 Toxicological Information

There is limited toxicological information on the human health effects associated with low-level exposures to chemicals in the environment. Most information available is based on epidemiological studies of occupationally exposed workers. These are usually based on an 8-hour day or 40-hour week, higher level exposure regimes and do not apply well to low-level, chronic exposures. Additionally, reference doses and cancer potency estimates for many chemicals are based on laboratory dose-response estimates in animals. The use of animals requires certain assumptions to be made, which introduces further uncertainty. Assumptions include:

- The toxicological effect in animals also occurs in humans.
- The short-term exposures used in animal studies can be extrapolated to chronic or long-term human exposures.
- The toxicokinetic and toxicodynamic processes that occur in animals also occur in humans.
- The uptake of the chemical from the test vehicle (the medium within which the test compound is delivered to the animals, e.g., water) will be representative of the uptake of the chemical from real-world environmental media (e.g., soil, biota).
- The assumption that extrapolation from high-dose laboratory studies to low-dose environmental studies accurately reflects the shape of the dose response curve at the low dose-response range.

To account for these and other related uncertainties, agencies such as Health Canada and the US EPA adopt conservative assumptions to account for uncertainties. The use of Uncertainty Factors accounts for uncertainties by lowering the toxicological reference value used in the HQ calculation well below the level where no effects were seen in animals. Uncertainty Factors are applied by factors of 10 to account for uncertainties such as interspecies differences (e.g., physiology), individual variation (e.g., unusually sensitive individuals), limitations in toxicological information, and extrapolation from acute exposures to chronic exposures. Depending on the degree of uncertainty, typical factors will range from 100 to 10,000, with some being lower than 10 (i.e., in the case where reliable human data are available). The incorporation of these factors results in risk estimates that are very conservative and limited exposures above reference doses or reference concentrations would not be expected to result in adverse human health effects.

Further, the HHRA has assumed that the relative absorption rate for each COPC via inhalation and ingestion is 100%. Some of TRVs used in this HHRA were determined from studies in which the effects were based on administered doses rather than absorbed doses. Because studies administer COPC in forms that are more readily absorbed that would be found in environmental media, the TRVs derived from these studies may overestimate the amount of COPC that would be absorbed by the human receptor. Thus, using these TRVs over-predicts the potential effects associated with the exposures experienced by the human receptors.

5.5.2 Sensitive Populations

A susceptible population will exhibit a different or enhanced response to a COPC than will most persons exposed to the same level of the chemical in the environment. The reasons for this may include genetic makeup, age (e.g., children or seniors), health and nutritional status, behaviour, and exposure to other toxic substances (e.g., cigarette smoke) (ATSDR 1998). Human receptors are selected such that the most sensitive individuals and individuals having the greatest potential for exposure to COPC and adverse responses from such exposures are represented. Because it was assumed that the Indigenous Receptor will rely exclusively on locally caught meat and rely on local fish and vegetation to supplement their diets, the Indigenous Receptor represents a high-level exposure scenario. The Indigenous Toddler Receptor would represent the most sensitive individual for non-carcinogens for the reasons just mentioned plus the physiological (nutritional needs) and behavioural (frequent hand to mouth transfer) considerations associated with the toddler age range. Non-carcinogenic TRVs used in this risk assessment were estimates of a continuous exposure for the human population, including sensitive subgroups (e.g. children, women of child-bearing age), that are to be without appreciable risk of adverse non-cancer effects during a lifetime.

Carcinogenic COPC exposures were assessed over the entire lifetime of a receptor, incorporating all life stages. As noted in Section 5.5.1, TRVs including cancer slope factors used in this HHRA have been derived by health agencies to be protective of sensitive populations (through the application of uncertainty factors).

5.5.3 Exposure Assessment

The air concentrations and deposition rates used in the HHRA were obtained directly from the air dispersion and deposition modelling results while future surface water concentrations were obtained directly from water quality modelling results. Conservative assumptions were used in the development of the air model and the predictive water quality model for the Project.

Maximum predicted 1-hour, 2-hour, 24-hour, and annual average concentrations in air at each receptor location were used to evaluate inhalation health risks associated with both short-term and long-term exposures. In reality, the frequency with which the maximum concentration would occur at any one receptor location is relatively low for most COPC. Therefore, the risk estimates tend to overestimate, rather than underestimate, health risks.

Estimation of COPC uptake through the food chain involves the use of assumptions regarding many factors, including the various uptake factors. Typically, these uptake factors are conservative and tend to overestimate, rather than underestimate, concentrations in biota. In addition, these uptake factors were applied to the reasonable maximum concentrations (e.g., soil concentrations at the end of operation, maximum surface water concentrations), and are assumed to remain constant throughout the lifetime of the receptor (e.g., 80 years for lifetime exposure); thus, the resulting exposure predictions are very conservative.

5.5.3.1 Market Basket Foods

The purpose of the HHRA is to assess the potential change in health risks for occupants of the Gordon region or the MacLellan region due to contributions from the Project. Human receptors in the Gordon or MacLellan regions are expected to be exposed to the same concentrations in market basket foods (i.e., supermarket food) as a typical Manitoba resident living outside the LAA. The chemical concentrations in market basket foods are not expected to change as a result of the Project as these foods come from centralized distribution centers and are generally grown and processed at variable sources outside the LAA/RAA. A number of exposures evaluated in the HHRA were specific to Indigenous receptors (e.g., the ingestion of country food); these exposures may not be relevant for a typical Manitoba resident. Potential Project-related health risks are evaluated by comparing the calculated risks to applicable benchmarks, rather than to risks of a typical Manitoba resident.

Calculated health risks for ingestion exposures (i.e., hazard quotients) were compared to a benchmark of 0.2 to account for the multiple potential pathways that can contribute to ingestion/dermal exposure. If all potential ingestion pathways were evaluated (including ingestion of market basket food) then the overall HQ could be compared to 1.0. By comparing to a benchmark of 0.2, the assessment has accounted for potential exposures from market basket foods.

5.5.3.2 Backyard Produce Consumption

Indigenous receptors and Residential receptors were assumed to obtain 10% of their overall vegetables intake from backyard produce, consistent with CCME (2006). It is likely that receptors will obtain most of their vegetables from supermarkets therefore the assumption that 10% of their intake comes from backyard produce is realistic.

5.5.3.3 Recreational Exposure to Water

Human health-based guidelines for recreational water use have been established for biological hazards and have not been established for chemicals. In Section 8.3 of the Guidelines for Canadian Recreational Water Quality (Health Canada 2012), Health Canada notes:

> *There is insufficient information to support the establishment of guideline values for specific chemical parameters in recreational waters. Risks associated with specific chemical water quality hazards will be dependent on the particular circumstances of the area in question and should be assessed on a case-by-case basis.*

In general, potential risks from exposure to chemical parameters will be much smaller than the risks from the microbiological hazards potentially present in recreation waters (WHO 2003). With chemical concentrations typically found in water, most recreational water users will not be exposed to concentrations necessary to elicit either an acute or chronic illness response.

For this reason, recreational water quality and the risks associated with exposure to metals in recreational water has not been included in the quantitative assessment of potential human health risks.

5.5.4 Receptor Characteristics

For each receptor scenario, published characteristics and professional judgment were used in determining exposure durations, consumption patterns and ingestion rates (e.g., Health Canada 2004, 2012; Chan et al. 2012). Wild meat, fish and traditional vegetation consumption rates specific to Indigenous populations were obtained from Chan et al. (2012). For this assessment, the fraction of the total diet that an Indigenous Receptor would obtain from the LAA (i.e., 10% for fish and backyard produce and 100% for wild meat, and traditional vegetation) represents a reasonable maximum exposure and overstates the potential risk.

5.5.5 Summary of Uncertainties

A summary of the important assumptions and uncertainties in the HHRA and the implications of these assumptions on risk estimates is provided in Table 5-110.

Table 5-110 Evaluation of Assumptions and Uncertainties Applied in the HHRA

Assumptions/Uncertainty	Discussion of Conservatism	Analysis Likely to Overestimate/ Underestimate Risk
Exposure Assessment		
For analyses of non-carcinogenic exposures both toddler and adult receptors were selected.	Toddlers represent the most sensitive age group for assessing non-carcinogenic effects. Resultant risks are generally over protective for an adult population; however, the adult exposures have been included as additional information. This approach is in accordance with standard practice (i.e., Health Canada and US EPA).	Neutral for Toddlers and Adults. The risks for toddlers overestimate risks for other age groups
Project is not currently in operation; therefore, future emissions and ground level air concentrations were predicted by air dispersion models.	The air models are designed to provide a realistic prediction of future air quality related to the Project.	Neutral
Behavioural and physical characteristics were assumed for receptors.	Behavioural and physical characteristics were chosen for receptors in an attempt to overestimate potential exposures to receptors. Additional receptor assumptions are outlined below.	Overestimate
Indigenous Receptors and Residential Receptors obtain 100% of their intake of wild meat from their region.	With respect to wild meat, this assumption is considered potentially realistic as one large animal (i.e., a moose) could represent a large portion of a family's meat consumption for a one-year period.	Overestimate
Indigenous Receptors and Residential Receptors obtain 100% of their intake of traditional plants from their region.	In the absence of community-specific consumption and use details for traditional foods, the assumption of 100% of traditional plants being obtained from a receptors region is considered very conservative, or an upper-bound limit, scenario for the Indigenous Receptor and the Residential Receptor.	Overestimate
Receptors were assumed to obtain 10% of the fish they consume on a yearly basis from Swede Lake (for Gordon region receptors) or Cockeram Lake (for MacLellan region receptors).	This is considered conservative, as information gathered through community and Indigenous engagement suggests that people obtain fish from lakes across the Gordon and MacLellan regions. Therefore, the assumption that 10% the fish an individual consumes on a yearly basis is harvested from either the Gordon region (Swede Lake) or the MacLellan region (Cockeram Lake) it considered conservative.	Neutral/Overestimate
Receptors were assumed to consume backyard garden produce, and it was further assumed that the consumption of backyard garden produce accounted for 10% of the yearly combined intake of root vegetables and other vegetables identified by Health Canada (2012).	This assumption is reasonable given the CCME assessment that concluded that a typical backyard garden can reasonably be expected to yield sufficient produce to account for 10% of an individual's yearly produce intake. Thus, assuming that backyard garden produce accounts for 10% of the total yearly produce intake is likely to over-estimate potential exposures in Baseline Case and Future Case conditions.	Neutral/Overestimate
Inhalation risks for the Off-Duty Worker were based on the time workers are expected to be present in the work camp.	This receptor is assumed to spend 12 hours per day, 26 weeks per year in the work camp, based on a 12-hour work day and a 14-day on/ 14-day off-shift rotation. The health of workers when they are working on the Project and not present in the permanent work camp is protected by occupational health and safety standards, codes and regulations established by various provincial and federal governments; thus, occupational health and safety is not addressed in the scope of this assessment.	Neutral for short-term exposures Neutral for long-term residential exposures Overestimate for non-resident long-term exposures
The surface water ingestion and sediment contact were not evaluated quantitatively.	These pathways are considered minor as locals do not obtain drinking water from the Surface Water LAAs of either region. Because no public beaches or areas of shoreline where high intensity activities occur were identified in the Gordon or MacLellan regions and locations where humans could be exposed to sediment are remote, exposure to sediment would be infrequent. In addition concentrations in surface water were less than the applicalbe drinking water guidelines, the concentrations in sediment were less than the applicable soil guidelines, or the change in concentration from Base Case to Future Case was minor (i.e,. less than 1%).	Neutral
For the Indigenous Receptor and Residential Receptor, in lieu of site-specific receptor characteristics for ingestion of traditional vegetation, fish and wild meat, a recent consumption study completed by Chan et al. (2012) was used.	Site-Specific receptor characteristics were not available. Chan et al. (2012) is a comprehensive consumption study of First Nation people living in Manitoba. The intake rates in Chan et al. (2012) are assumed to be representative of Indigenous people living in Manitoba, including those that may visit the LAA. In addition, the purpose of an EA is to evaluate the change in exposure as a result of the Project. The intake rates affect the magnitude of the exposures, but do not affect the proportional changes. Therefore, the use of literature-based intake rates rather than site-specific ones is not expected to change the conclusions.	Overestimate
For assessment of carcinogenic ingestion risk, it was assumed Indigenous and Residential receptors would be present in their region 24-hours/day, 7 days/week, 52 weeks/year for 80 years (i.e., from birth to 80 years of age).	This is a conservative assumption as the assessment did not consider any time spent away from the location during the 80-year exposure period for carcinogenic compounds.	Overestimate
COPC-specific ground-level air concentrations and deposition data were used to predict various environmental media concentrations (e.g., soil, surface water, plant tissue). Environmental media concentrations were predicted assuming deposition in the regions had already occurred for 13 years (i.e., life of mine)	Region-specified 95% UCLM deposition rates and ground level air concentrations were used to predict COPC concentrations in environmental media (i.e., soil, vegetation). This is a conservative assumption in that it is likely that deposition rates would vary over the assessment area.	Overestimate

Table 5-110 Evaluation of Assumptions and Uncertainties Applied in the HHRA

Assumptions/Uncertainty	Discussion of Conservatism	Analysis Likely to Overestimate/ Underestimate Risk
	Additionally, deposition was assumed to have occurred over the 13-year operation phase of the Project. This is a conservative assumption in that it assumes the COPC concentrations would be at their maximum concentrations in environmental media over the 80-year receptor lifetime.	
Food chain uptakes	Estimation of COPC uptake through the food chain involves the use of assumptions regarding many factors, including root uptake factors, air to plant transfer factors, biotransfer and bioconcentration factors, and crop and soil ingestion rates (MOE 2008; US EPA 1997). Where it was necessary to model Baseline Case as well as Future Case concentrations, these assumptions apply equally to both cases and therefore have no net effect on the incremental change in concentrations between Baseline Case and Future Case.	Neutral
Did not evaluate infants exposed to COPC in breast milk	This is a minor pathway as metals are not expected to accumulate in breast milk. Mercury in breast milk could represent a potential health concern; however, the increases in mercury concentrations in environmental media as a result of the Project are expected to be negligible.	Neutral
Receptors present in the LAA during the winter months were assumed to be exposed to soil.	Soil exposure is unlikely to occur during the winter months when the ground is frozen and/or snow covered.	Overestimate
Exclusion of market basket foods	Concentrations in market basket food are not anticipated to be affected by the Project. Potential health risks are compared to a HQ benchmark of 0.2 due to potential contributions from multiple sources such as market basket food. Therefore, exclusion of market basket food is not anticipated to affect the conclusions of the HHERA.	Neutral
Toxicity Assessment		
Selected TRVs from the current toxicological values available (e.g., Health Canada, US EPA Integrated Risk Information System)	This approach is in accordance with standard practice, and provides the current scientific basis with which to conduct a risk assessment.	Neutral
Toxicity Reference Values (TRV)	For the derivation of TRV for use in HHRA ,regulatory bodies adopt conservative assumptions to account for uncertainties (i.e., interspecies differences, individual variation, limitations in toxicological information, and extrapolation from acute to chronic exposures). Depending on the degree of uncertainty, typical factors will range from 100 to 10,000, with some being lower than 10 (in the case where solid human data is available). The incorporation of these factors results in risk estimates that are very conservative and limited exposures above reference doses or reference concentrations would not be expected to result in adverse human health effects.	Overestimate
Risk Characterization		
For evaluating exposures non-carcinogenic COPC in air, a target benchmark CR of 1.0	CRs are only applicable to exposure to air in the inhalation assessment. Because 100% of inhalation exposure is from one media (i.e., air concentrations), the toxicity reference values or health-based benchmarks are inhalation-specific, it is appropriate to set the CR benchmark value at 1.0. The approach used is common risk assessment practice in Canada when completing an inhalation assessment.	Neutral
For evaluating exposures to non-carcinogenic COPC, a target benchmark HQ of 0.2 was used.	The use of an HQ benchmark of 0.2 is conservative as it allows 80% of the tolerable daily intake of a chemical to be received from other sources, including background.	Neutral
ILCR set to 1 in 100,000 (10^{-5}) for evaluating exposures to carcinogenic COPC at the site.	This value has been adopted by Health Canada to represent an “acceptable” benchmark risk for carcinogenic substances.	Neutral
ADAFs	Age dependent adjustment factors are applied to account for the potential increase in carcinogenic potency of a mutagenic chemical in young children (infants, toddlers, children) when exposures occur during early stages of life. The Project has a 13-year operational life which means that young children could be exposed to Project-related chemicals during early life-stages. Children born at the start of the Project could experience a maximum of 13 years of early life-stage exposure to Project-related chemicals. Using the ADAF values and age ranges for infants (10, 0.5 years), toddlers (5, 4.5 years), children (3, 7 years) and teens (2, 1 year (age 13)) (Health Canada 2013), the ADAF that would be applied to the LADDs would be calculated as follows: ((10 x 0.5) +(5 x 4.5) + (3 x 7) + (2 x 1)))/13 = 3.9. The ADAF would be applied to the CR estimates for receptors in the Gordon and MacLellan regions where young children (0 – 13 years of age) could be expected to be present. The maximum inhalaiton CR calculated for a carcinogenic COPC which is mutagenic, was 2.9E-06 (Chromium VI in the MacLellan region). A carcinogenic CR of 2.9E-06 is equivalent to a ILCR of 2.9 x 10^{-11} which is below the 10^{-5} cancer risk acceptabbility benchmark established by Health Canada. Applying an ADAF of 3.9 to this would increase the ICLR to 1.1x 10^{-10} which is also below the 10^{-5} cancer risk acceptability benchmark. The CRs for the other carcinogenic COPC, calculated for Indigenous and Residential receptors in the Gordon and MacLellan regions were all lower than the CRs calculated for Chromium VI, and ILCRs calculated for thse compounds by applying the ADAF to the ICLRs for these compounds would still be below the 10^{-5} risk acceeptability benchmark. Thus, applying the ADAF to the cancer risk calculations would not alter the conclusions of the HHRA.	Small underestimate/Neutral

5.6 HHRA SUMMARY

5.6.1 Gordon Region

The HHRA evaluated potential human health risks associated with exposures to Project-related chemicals of potential concern (COPC) under Baseline Case and Future Case conditions for Indigenous and Residential receptors in the Gordon region. The results demonstrated that the predicted changes in ingestion-related exposures to carcinogenic and non-carcinogenic COPC between Baseline Case and Future Case conditions, represents a negligible change in human health risk for the Indigenous and Residential receptors.

The HHRA identified no Project-related carcinogenic inhalation health risks above the applicable benchmark. Project-related non-carcinogenic health risk were below the applicable benchmark with the exception of 1-hour NO_2 exposures for Indigenous and Residential Receptors in the Gordon region.

In the Gordon region, exceedances of the 2025 1-hour NO_2 CAAQS are predicted at three special receptor locations, Potential Indigenous Receptor 24 (east of the Gordon PDA), Potential Indigenous Receptor 25 (northeast of the Gordon PDA) and Potential Indigenous Receptor 27 (north of the Gordon PDA). The exceedances are predicted to occur during the colder months (December through May) and to occur overnight sometime between 20:00 and 6:00 the following morning. Within this period, there is no fixed pattern to when individual exceedances happen. The maximum 1-hour NO_2 concentration was predicted to occur at Potential Indigenous Receptor 27. Information provided in the Traditional Land and Resources Use studies and in the Manitoba Métis Traditional Knowledge, Land Use, and Occupancy Study for the Lynn Lake Gold Mine Project (SVS 2020), do not identify habitations in the vicinity of the Potential Indigenous Receptor 27 special receptor location, or in the vicinities of the other two special receptor locations where exceedances of the 1-hour NO_2 2025 CAAQS, are predicted to occur. In the absence of habitation near these special receptor locations, it is less likely that people would be present in these areas at the time of day when then these exceedances are predicted to occur, than if the exceedances were to occur during daylight hours. In addition, the maximum 1-hour NO_2 concentrations for all 5 years at each of these three special receptor locations are below the Health Canada short-term Residential Indoor Air Quality Guideline (RIAQG) for NO_2 of 170 $\mu g/m^3$, and the predicted annual average NO_2 concentrations are below the 2025 annual average NO_2 CAAQS. Predicted annual average NO_2 concentrations at the remaining 44 special receptor locations within the Gordon region are also below the annual average CAAQS.

Based on the results, it is reasonable to conclude that occasional exceedances of the 2025 1-hour NO_2 CAAQS represent a negligible human health risk for people who may be in the area. Therefore, Project related health risks associated with inhalation exposures to the carcinogenic and non-carcinogenic COPC are negligible.

5.6.2 MacLellan Region

The HHRA evaluated potential human health risks associated with exposures to Project-related COPC under Baseline Case and Future Case conditions for Indigenous and Residential receptors in the MacLellan region. The results demonstrated that the predicted changes in ingestion-related exposures to carcinogenic and non-carcinogenic COPC between Baseline Case and Future Case conditions, represents a negligible change in human health risk for the Indigenous and Residential receptors.

The HHRA identified no Project-related carcinogenic inhalation health risks above the applicable benchmark. Project-related non-carcinogenic health risk were below the applicable benchmark with the exception of 1-hour NO_2 exposures for Indigenous and Residential Receptors in the MacLellan region. In the MacLellan region, exceedances of the 2025 1-hour NO_2 CAAQS are predicted at four special receptor locations, Potential Indigenous Receptor 36 (north of the MacLellan PDA), Potential Indigenous Receptor 37, Potential Indigenous Receptor 38 (both located southwest of the MacLellan PDA) and Waste Disposal Site 1 (located southeast of the MacLellan PDA), the maximum predicted 1-hour NO_2 concentration exceeded the 2025 1-hour NO_2 CAAQS. However, of the four special receptor locations within the MacLellan region where 1-hour NO_2 exceedances were predicted to occur, the Waste Disposal Site location is unlikely to represent a location people would be expected to frequent. The three remaining special receptor locations where 1-hour NO_2 exceedances are predicted to occur represent locations that people could reasonably be expected to frequent. Of these three locations, the highest number of exceedances of the 1-hour NO_2 2025 CAAQS are predicted to occur at Potential Indigenous Receptor 37 (163 exceedances over the 43,800 hours modelled over the 5-year modelling period). This represents 0.37% of the time.

At Potential Indigenous Receptor 37, and the other receptor locations, exceedances are predicted to occur during the colder months (December through May) and to occur overnight sometime between 20:00 and 6:00 the following morning. Within this period, there is no fixed pattern to when individual exceedances happen. The maximum 1-hour NO_2 concentration was predicted to occur at Potential Indigenous Receptor 37. Information provided in the Traditional Land and Resources Use studies and in the Manitoba Métis Traditional Knowledge, Land Use, and Occupancy Study for the Lynn Lake Gold Mine Project (SVS 2020), do not identify habitations in the vicinity of the Potential Indigenous Receptor 37 special receptor location, or in the vicinities of the other two special receptor locations where exceedances of the 1-hour NO_2 2025 CAAQS, are predicted to occur. In the absence of habitation near these special receptor locations, it is less likely that people would be present in these areas at the time of day when then these exceedances are predicted to occur, than if the exceedances were to occur during daylight hours. In addition, the maximum 1-hour NO_2 concentrations for all 5 years for each of these three special receptor locations are below the Health Canada short-term Residential Indoor Air Quality Guideline (RIAQG) for NO_2 of 170 $\mu g/m^3$, and the predicted annual average NO_2 concentrations are below the 2025 annual average NO_2 CAAQS. Predicted annual average NO_2 concentrations at the remaining 110 special receptor locations within the MacLellan region are also below the annual average CAAQS.

Based on the results, it is reasonable to conclude that occasional exceedances of the 2025 1-hour NO_2 CAAQS represent a negligible human health risk for people who may be in the area. Therefore, Project related health risks associated with inhalation exposures to the carcinogenic and non-carcinogenic COPC are negligible.

5.6.3 Work Camp

The HHRA identified no Project-related carcinogenic inhalation health risks above the applicable benchmark. Project-related non-carcinogenic health risk were below the applicable benchmark with the exceptions of 1-hour NO_2, and 2-hour DPM exposures for Off-Duty Workers housed at the work camp.

At the work camp the predicted 1-hour NO_2 exceedances usually occur in winter months (December–March). These exceedances generally happen overnight, occurring sometime between 19:00 and 6:00 the following morning. Within this period, there is no fixed pattern to when individual exceedances happen. In addition, in the winter months, between 19:00 and 6:00 workers would generally be expected to spend off-duty time indoors, and thus would not be expected to experience prolonged exposures to NO_2 concentrations that exceed the 1-hour CAAQS.

The DPM concentrations are predicted to exceed the 2-hour air quality standard of 10 µg/m^3 on two occasions (10.4 µg/m^3 and 11.5 µg/m^3) over a 5-year modelling period. Thus, exceedances of the 2-hour DPM air quality standard are rare. The 2-hour DPM air quality standard is based on a lowest observable adverse effect level (LOAEL) of 100 µg/m^3 from studies where increased respiratory resistance was reported in study groups that included subjects that were mildly asthmatic (Health Canada, 2016c). Thus, given that the predicted exceedances of the short-term (2-hour) exposure limit are small and of short duration, and that the health effects associated the 2-hour limit are based on mild and reversible effects in sensitive members of the population (asthmatics), and the fact that the maximum predicted annual average exposure for an Off-Duty Worker is below the annual average exposure limit, it is reasonable to conclude that for Off-Duty Workers, inhalation exposures to DPM represents a negligible human health risk.

Considering the results of the assessment of potential health risks associated with inhalation exposures to NO_2, and DPM it is reasonable to conclude that inhalation exposure to NO_2, and DPM a represent negligible human health risks for Off-Duty Workers housed at the work camp.

6.0 ECOLOGICAL RISK ASSESSMENT

The purpose of an ERA is to evaluate the potential that ecological receptors (such as mammals, birds, plants, fish) may experience adverse health effects as a result of exposure to chemical stressors. For this ERA, adverse effects refer to toxicologically induced changes in the health of ecological receptors that may be exposed to COPC released into the environment, specifically the LAA, as a result of Project-related activities. Like the HHRA, the framework used in this ERA follows the standard risk assessment paradigm comprised of five stages: Problem Formulation, Exposure Assessment, Toxicity Assessment, Quantitative Risk Characterization and an Uncertainty Assessment.

6.1 PROBLEM FORMULATION

The Problem Formulation stage is an information gathering and interpretation stage that focuses the assessment on the primary areas of concern for the Project. This stage usually includes management, assessment and protection goals (and associated acceptable effect levels), a review of the regulatory context for the ERA, site characterization, the selection of ecological receptors, the identification of COPC, and the assessment of potential exposure pathways linking the two.

The Problem Formulation culminates in a conceptual site model, which provides a visual depiction of the relevant pathways linking COPC in various environmental media and biota to the ecological receptors and biota of interest. Management goals, regulatory context, site characterization and COPC were already identified in Section 1.0 through Section 4.0, so in the following sections, the ecological receptors and exposure pathways from the Project are discussed as well as the protection goals and acceptable effect levels associated with the ERA.

6.1.1 Ecological Receptors of Concern

6.1.1.1 Selection of Ecological Receptors

Wildlife habitat in the RAA is a mosaic of terrestrial and wetland habitats intersected by extensive stream and lake systems that are relatively undisturbed. Numerous wildlife species inhabit the RAA due to the widespread availability of wetlands, rivers, lakes and forests. With the large number of wildlife species present in the RAA, it is neither practical nor necessary to conduct an assessment for each species. Rather, after reviewing the known species inventories of the RAA (Section 3.1) a representative subset of ecological receptors (also known as receptors of concern, or ROC, or valued ecosystem components, or VECs) was selected as the basis for this ERA. Ecological receptors were chosen for the ERA by considering wildlife species that are:

- Indigenous to the area.
- Most likely to receive the greatest exposure to chemical emissions due to their habitat and home range.
- Representative of various levels in the aquatic and terrestrial trophic web (e.g., carnivore, herbivore, insectivore, piscivore).
- Suitable surrogates for federal and provincial species at risk that could be in the RAA.
- Of cultural, economic, or social significance.

The selected ecological receptors are considered representative of other species occupying a similar position in the food web in order that results of the Risk Characterization stage for a selected ecological receptor can be used to make inferences about risk to other species occupying a similar trophic level or guild. For example, if results of the ERA indicate that no unacceptable risk is expected for American robin, a species that relies on a diet of soil invertebrates, then no unacceptable risks would be expected for other insectivorous bird species. Using these criteria, the ecological receptors assessed in the ERA (Table 6-1) are expected to provide an adequate and conservative representation of the faunal and floral diversity in the RAA. Reptiles (e.g., turtles and snakes) are not expected to occur in the RAA, and thus are not included in this assessment.

Table 6-1 Ecological Receptors Selected for the ERA

Common Name of Ecological Receptor	Scientific Name of Ecological Receptor	Feeding Guild
Mammals		
American beaver	*Castor canadensis*	Herbivorous mammal (aquatic)
American mink	*Neovison vison*	Omnivorous mammal (semi-aquatic)
Black bear	*Ursus americanus*	Omnivorous large mammal (terrestrial)
Common masked shrew	*Sorex cinereus*	Insectivorous mammal (terrestrial)
Deer mouse	*Peromyscus maniculatus*	Omnivorous small mammal (terrestrial)
Meadow vole	*Microtus pennsylvanicus*	Herbivorous small mammal (terrestrial)
Moose	*Alces alces*	Herbivorous large mammal (terrestrial)
Muskrat	*Ondatra zibethicus*	Herbivorous mammal (aquatic)
Northern river otter	*Lontra canadensis*	Piscivorous mammal (aquatic)
Short-tailed weasel	*Mustela erminea*	Carnivorous mammal (terrestrial)
Snowshoe hare	*Lepus americanus*	Herbivorous small mammal (terrestrial)
Woodland caribou	*Rangifer tarandus caribou*	Herbivorous large mammal (terrestrial)
Birds		
American robin	*Turdus migratorius*	Omnivorous bird (terrestrial)
Barn swallow	*Hirundo rustica*	Insectivorous bird (terrestrial)
Common loon	*Gavia immer*	Piscivorous bird (aquatic)
Lesser scaup	*Aythya affinis*	Insectivorous bird (aquatic)
Mallard	*Anas platyrhynchos*	Omnivorous bird (aquatic)
Red-tailed hawk	*Buteo jamaicensis*	Carnivorous bird (terrestrial)
Spotted sandpiper	*Actitis macularius*	Omnivorous bird (aquatic)
Spruce grouse	*Falcipennis canadensis*	Herbivorous bird (terrestrial)
Herptiles		
Wood frog	*Lithobates sylvaticus*	Insectivorous amphibian (terrestrial)
Community Receptors		
Terrestrial plant communities	Various	Various
Terrestrial invertebrate communities	Various	Various
Benthic communities	Various	Various
Aquatic communities	Various	Various

6.1.2 Mammalian Ecological Receptor Profiles

6.1.2.1 American Beaver

The American beaver (*Castor canadensis*) is primarily a nocturnal mammal that lives a semi-aquatic lifestyle. Beavers construct bank dens and lodges, which are used for protection from predators and weather. Where beavers live exclusively in rivers or deep lakes, bank dens are typical, while lodges are built in ponds, shallow lakes, or on the shore. Individual beavers spend most of their lives in small extended-family units traditionally called colonies. Established colonies inhabit discrete and defended territories; therefore, beaver activity is restricted to a well-defined area within close range of the lodge (Baker and Hill, 2003). The home range of a beaver depends on sex, age, social organization of the family unit, type of occupied habitat, and seasonal constraints. The home range in the summer is 0.08 to 0.18 km^2, with smaller ranges in fall and winter (Baker and Hill, 2003). An adult beaver weighs from 16 to 32 kg (CWS & CWF, 2005). Beavers are generalist herbivores that feed on a wide variety of herbaceous and woody terrestrial plants. Herbaceous plants can account for up to 90% of the diet in summer and up to 50% during spring and fall. Woody material may constitute up to 86% of the diet in winter and 16% in summer (Svendsen, 1980). Beavers also consume aquatic plants. Beavers occupying ponds appear to shift to a more aquatic diet in winter. Studies show that aquatic plants may compose 12% to 80% of the beaver's diet, depending on the season and the type of habitat occupied (Milligan and Humphries, 2010). For the present assessment, the beaver's diet was assumed to be 55% terrestrial plants and 45% aquatic plants. Based on the US EPA's food ingestion rates for rodents (US EPA, 1993b) and an average body weight of 24 kg, for this assessment a beaver is assumed to consume 0.022 kg of wet weight food, per kg body weight, per day and 0.072 L of water, per kg body weight, per day. The beaver is estimated to incidentally ingest approximately 3.9E-03 kg/day of dry soil and 6.2E-03 kg/day of dry sediment.

6.1.2.2 American Mink

The American mink (*Neovison vison*) is a small member of the weasel family and is the most abundant and widely distributed carnivorous mammal in North America (US EPA, 1993b). Mink are active year-round and occupy aquatic habitats such as rivers, streams, lakes, ditches, swamps, marshes and backwater areas (US EPA, 1993b). In winter, mink spend more time near dens and use a smaller portion of their home range than in summer. Adult male home ranges are generally larger than adult female home ranges. The average home range for females is 0.08 to 0.2 km^2, while that of males may be more than 7 km^2 (NatureServe, 2019). The area of their foraging range varies from 0.06 to 16.3 km^2 (FCSAP, 2012). Mink are skilled swimmers and climbers. In searching for food, they can swim up to 30 meters underwater and dive to depths of 5 meters (Schlimme, 2003). An average sized American mink weighs approximately 0.82 kg (FCSAP, 2012). The diet of mink varies with the season. During the summer it consists of crayfish, fish, frogs, small mammals such as shrews, rabbits, mice, muskrats and water fowl. In the winter, they primarily prey on mammals (US EPA, 1993b; Schlimme, 2003). Mink consume approximately 0.14 kg of wet weight food, per kg body weight, per day and 0.037 L of water, per kg body weight, per day (FCSAP, 2012). For the present assessment, the mink's diet was assumed to be 25% terrestrial prey items, 10% benthic invertebrates and 65% fish. The mink is estimated to incidentally ingest approximately 1.8E-04 kg/day of dry soil and 4.3E-04 kg/day of dry sediment.

6.1.2.3 Black Bear

The American black bear (*Ursus americanus*) is found throughout most of Canada. Black bears prefer heavily wooded areas and dense bushland (CWS & CWF, 2007). Not a true hibernator, the black bear enters its den in October to December and emerges in March to early May (Kronk, 2007). Mean home ranges are 10 to 40 km^2 for females and often more than 100 km^2 for males (CWS & CWF 2007). Their foraging range varies from 3 to 1147 km^2 (FCSAP, 2012). An average sized black bear weighs approximately 68 kg (FCSAP, 2012). Black bears consume primarily grasses and forbs in spring, shrub and tree-borne fruits in summer, and a mixture of hard and soft mast in fall. Only a small portion of the diet consists of animal matter, colonial insects (e.g., ants) and beetles. Most vertebrates are consumed in the form of carrion (Kronk, 2007). When available, they may also supplement their diet with fish (CWS & CWF, 2007). Black bears consume approximately 0.03 kg of dry weight food (or 0.19 kg of wet weight food), per kg body weight, per day and 0.064 L of water per kg body weight, per day (FCSAP, 2012). For the present assessment, the black bear's diet was assumed to be 80% terrestrial plants, 5% terrestrial invertebrates, 10% terrestrial prey and 5% freshwater fish. Based on the consumption of these foods, the black bear is estimated to incidentally ingest approximately 4.1E-02 kg/day of dry soil and 3.2E-03 kg/day of dry sediment.

6.1.2.4 Common Masked Shrew

The masked shrew (*Sorex cinereus*) is the most widely distributed shrew in North America, and is found throughout most of Canada (Lee, 2001). It is common in open and closed forests, meadows, riverbanks, lakeshores, and willow thickets (Lee, 2001). The average home and foraging range of the masked shrew is 0.006 km^2 (Lee, 2001; FCSAP, 2012). An average sized masked shrew weighs approximately 0.004 kg (FCSAP, 2012). Shrews are prey for many small predators such as weasels, hawks, falcons, owls, domestic cats, foxes, snakes, and short-tailed shrews (Lee, 2001). Although not strictly nocturnal, most of their activity takes place at night, hunting primarily on the ground and sometimes climbing into low vegetation and shrubs. The masked shrew primarily feeds on invertebrates including, insect larvae, ants, beetles, crickets, grasshoppers, spiders, harvestmen, centipedes, slugs, and snails. They also opportunistically consume seeds and fungi (Lee, 2001). Masked shrew consume approximately

0.34 kg of dry weight food (or 2.1 kg of wet weight food), per kg body weight, per day and 0.17 L of water, per kg body weight, per day (FCSAP, 2012). For the present assessment, the masked shrew's diet was assumed to be 5% terrestrial plants and 95% terrestrial invertebrates. Based on its consumption of these foods, the masked shrew is estimated to incidentally ingest about 2.8E-05 kg/day of dry soil.

6.1.2.5 Deer Mouse

The deer mouse (*Peromyscus maniculatus*) is a small rodent, common in woodland ecosystems throughout North America. An average sized deer mouse weighs 0.02 kg (FCSAP, 2012). The home range of the deer mouse varies from 0.0002 to 0.003 km^2 (Bunker, 2001) and foraging ranges vary from 0.0001 to 0.004 km^2 (FCSAP, 2012). Deer mice move along the forest floor beneath the concealing cover of the leaf litter, and they nest in well hidden burrows, rock crevices, brush piles and tree holes. Deer mice are nocturnal. They are a semi-arboreal species and can also swim, sometimes foraging in shallow water (Saunders, 1988; Bunker, 2001). Deer mice are prey items for night-hunting predators such as snakes, owls, and various carnivorous mammals. Deer mice are omnivorous; their diet consists of insects and other invertebrates, seeds, fruits, grains, fungi, flowers and nuts (Bunker, 2001). Deer mice consume approximately 0.27 kg of wet weight food, per kg body weight, per day and 0.19 L of water per kg body weight, per day (FCSAP, 2012). For the present assessment, the deer mouse's diet was assumed to be 50% terrestrial plants and 50% terrestrial invertebrates. Based on the consumption of these foods, the deer mouse is estimated to incidentally ingest approximately 1.8E-05 kg/day of dry soil.

6.1.2.6 Meadow Vole

The meadow vole (*Microtus pennsylvanicus*) is the most widely distributed small grazing herbivore in North America. It inhabits moist to wet habitats including grassy fields, marshes, and bogs (US EPA 1993b). It is a small rodent (approximately 0.035 kg) that is active year-round, making its burrows along surface runways in grasses or other herbaceous vegetation (US EPA, 1993b; FCSAP, 2012). The home range of the meadow vole varies from 2.0E-06 km^2 in winter to 8.0E-04 km^2 in summer (US EPA 1993b) and their mean foraging range is 6.9E-05 km^2 (FCSAP, 2012). Meadow voles are a major prey item for predators such as hawks and foxes. They feed primarily on vegetation such as grasses, leaves, sedges, seeds, roots, bark, fruits, and fungi, but will occasionally feed on insects and animal matter (US EPA, 1993b). The meadow vole consumes approximately 0.33 kg of wet weight food, per kg body weight, per day and 0.21 L of water per kg body weight, per day (FCSAP, 2012). For the present assessment, the meadow vole's diet was assumed to be 100% terrestrial plants. Based on its consumption of these foods, the meadow vole is estimated to incidentally ingest approximately 4.1E-05 g/day of dry soil.

6.1.2.7 Moose

The moose (*Alces alces*) can be found inhabiting forests from the Alaskan boundary to the eastern tip of Newfoundland and Labrador (CWS & CWF, 1997). Their geographic distribution follows, but is not confined to, the boundaries of the boreal forest. Moose are highly dimorphic between sexes, with cows weighing much less than bulls. The mean body weight (for both sexes) is 400 kg, although bulls of the northern sub-species, *A. A. gigans*, can weigh as much as 800 kg (CWS & CWF, 1997; FCSAP, 2012). Seasonal home ranges seldomly exceed 51 km^2, while annual home ranges can be up to 1932 km^2 depending on habitat and food availability (Hundertmark, 2007). Their foraging range varies from 4.6 to 262 km^2 (FCSAP, 2012). Seasonal migration usually follows an elevational gradient, as moose seek higher grounds in summer and lower elevations in winter (Innes, 2010). Moose are entirely herbivorous, consuming a mixture of terrestrial and aquatic vegetation. In the summer, moose prefer to browse on new growth of trees and shrubs (leaves, twigs, and bark), and vegetation associated with water (high-sodium aquatic plants). In the winter, their diet is typically restricted to conifer and hardwood twigs (NatureServe, 2019). A moose will consume approximately 0.02 kg of dry weight food (or 0.13 kg of wet weight food), per kg body weight, per day and 0.054 L of water, per kg body weight, per day (FCSAP, 2012). For the present assessment, the moose's diet was assumed to be 80% terrestrial plants and 20% aquatic plants. Based on its consumption of these foods, the moose was estimated to incidentally ingest 1.2E-01 kg/day of dry soil and 2.6E-02 kg/day of dry sediment.

6.1.2.8 Muskrat

The muskrat (*Ondatra zibethicus*) is an aquatic rodent that is common throughout Canada, living in saltwater and brackish marshes, freshwater creeks, streams, lakes, marshes, and ponds (US EPA, 1993b). Muskrats use space within linear home ranges, with most movements occurring near established dens or burrows. The average linear home range in a riparian habitat is reported to be 0.58 km (Ahlers et al., 2010). The area of their foraging range varies from 0.0003 to 0.008 km^2 (FCSAP, 2012). An average sized muskrat weighs approximately 1.0 kg (FCSAP, 2012). Muskrat are prey for many species including foxes, hawks, minks, and otters. Muskrats are primarily herbivorous and usually feed at night on aquatic vegetation growing near their dens. The roots and basal portions of aquatic plants make up most of the muskrat's diet, although shoots, bulbs, tubers, stems, and leaves also are eaten. They may also consume crayfish, molluscs, fish, frogs, turtles, and young birds (US EPA, 1993b). Active year-round, muskrats consume approximately 0.07 kg of dry weight food (or 0.46 kg of wet weight food), per kg body weight, per day and 0.099 L of water, per kg body weight, per day (FCSAP, 2012). For the present assessment, the muskrat's diet was assumed to be 80% aquatic plants, 15% benthic invertebrates and 5% fish. Based on its consumption of these foods, the muskrat was estimated to incidentally ingest 1.4E-03 kg/day of dry sediment.

6.1.2.9 Northern River Otter

The northern river otter (*Lontra canadensis*) occurs throughout Canada. It inhabits streams, rivers, estuaries, lakes, marshes and swamps (US EPA, 1993b; Ellis 2003). Their home range is typically linear and can vary from 2 to 78 km depending on the habitat type and the availability of food resources (Ellis, 2003). The area of their foraging range varies from 9 to 231 km^2 (FCSAP, 2012). An average sized river otter weighs approximately 7.5 kg (FCSAP, 2012). Otters are preyed upon by bigger mammals and birds of prey. They primarily eat fish but may also opportunistically consume crustaceans (e.g., crayfish), benthic invertebrates, birds, small mammals, reptiles and amphibians (US EPA, 1993b; Ellis, 2003). Active year-round (US EPA, 1993b), river otters consume approximately 0.03 kg of dry weight food (or 0.12 kg wet weight food), per kg body weight, per day and 0.081 L of water, per kg body weight, per day (FCSAP, 2012). For the present assessment, the river otter's diet was assumed to be 5% terrestrial prey, 15% benthic invertebrates and 80% fish. Based on its consumption of these foods, the river otter was estimated to incidentally ingest 2.9E-04 kg/day of dry soil, and 4.2E-03 kg/day of dry sediment.

6.1.2.10 Short-tailed Weasel

The short-tailed weasel or ermine (*Mustela erminea*) is found in the north temperate regions of North America in riparian woodlands, marshes, shrubby fencerows, and open areas adjacent to forests or shrub borders (Loso, 1999). An average sized ermine weighs 0.09 kg (FCSAP, 2012). Ermine home ranges vary from 0.1 to 0.2 km^2; home ranges of males are usually twice the size of female home ranges (Loso, 1999). Foraging ranges vary from 0.01 to 0.87 km^2 (FCSAP, 2012). Ermine are carnivores that hunt primarily at night. They mainly prey on small, warm-blooded vertebrates, preferring mammals of rabbit size and smaller. When mammalian prey is scarce, ermine may eat birds, eggs, frogs, fish, and insects (Loso, 1999). On average, ermine will consume approximately 0.11 kg of dry weight food (or 0.33 kg wet weight food), per kg body weight, per day and 0.13 L of water, per kg body weight, per day (FCSAP, 2012). For the present assessment, the ermine's diet was assumed to be 100% terrestrial prey items. Based on this diet, the ermine is estimated to incidentally ingest 1.9E-04 kg/day of dry soil.

6.1.2.11 Snowshoe Hare

The snowshoe hare (*Lepus americanus*) is found in every province and territory throughout Canada (CWS & CWF, 2005). Snowshoe hares weigh approximately 1.3 kg (FCSAP, 2012). The snowshoe hare tends to inhabit forests, swamps, and riverside thickets (US EPA, 1993b). It has a home range of approximately 0.04 km^2 (US EPA, 1993b) and a foraging range from 0.016 to 0.10 km^2 (FCSAP, 2012). The snowshoe hare is a frequent prey item, making it a keystone species in boreal forest food webs (CWS & CWF, 2005). Active year-round, it feeds on herbaceous plants and leaves in summer, and small twigs, buds, and bark in winter (CWS & CWF, 2005). The snowshoe hare consumes approximately 0.06 kg of dry weight food (or 0.40 kg wet weight food), per kg body weight, per day and 0.096 L of water per kg body weight, per day (FCSAP, 2012). For the present assessment, the snowshoe hare's diet was assumed to be 100% terrestrial plants. Based on its consumption of these foods, the snowshoe hare is estimated to incidentally ingest 4.9E-03 kg/day of dry soil.

6.1.2.12 Woodland Caribou

The woodland caribou (*Rangifer tarandus caribou)* includes several ecotypes (e.g., boreal, northern, mountain), which are defined on the basis of distinct patterns of habitat use and diet/feeding behaviour. The RAA lies within Environment Canada's Manitoba North boreal caribou range. Boreal caribou require large tracts of uninterrupted, lichen-rich mature coniferous forests interspersed by peatland complexes (Government of Canada, 2012). Boreal Caribou exist in small, dispersed, relatively sedentary bands throughout the year. The winter and summer ranges typically overlap and habitat use does not differ by season. The average home range of the boreal caribou is 710 km^2. Caribou are herbivores, foraging primarily on terrestrial lichens and to a lesser extent on arboreal lichens during winter. Winter foraging occurs primarily in open forests in peatlands and in nearby lichen-rich pine stands where available. Their summer diet consists of a wide variety of vegetation (BC MOE, 2004). A woodland caribou will consume approximately 0.051 kg of wet weight food, per kg body weight, per day and 0.059 L of water, per kg body weight, per day (Nagy, 1987). For the present assessment, the caribou's diet was assumed to be 100% terrestrial plants. Based on its consumption of these foods, the caribou was estimated to incidentally ingest 1.7E-01 kg/day of dry soil.

6.1.3 Avian Ecological Receptor Profiles

6.1.3.1 American Robin

The American robin (*Turdus migratorius*) is the largest, most abundant and broadly distributed thrush in North America. The breeding habitat of the robin includes moist forest, swamps, open woodlands, orchards, parks and lawns (US EPA, 1993b). During the non-breeding season, robins migrate to lower elevations and latitudes. However, not all populations are migratory-some spend the winter months close to their breeding grounds (Vanderhoff et al., 2016). The robin's home range is approximately 0.002 to 0.008 km^2 (US EPA, 1993b), while the foraging range varies from 0.007 to 0.28 km^2 (FCSAP, 2012). An average sized American robin weighs 0.08 kg (FCSAP, 2012). Its diet is highly variable throughout the year, changing from primarily soft-bodied invertebrates (e.g., earthworms) in spring and summer, to primarily fruit in autumn and winter (Vanderhoff et al., 2016).The American robin consumes approximately 1.2 kg of wet weight food, per kg body weight, per day and 0.14 L of water, per kg body weight, per day (FCSAP, 2012). For the present assessment, the robin's diet was assumed to be 60% terrestrial plants and 40% terrestrial invertebrates. Based on its consumption of these foods, the American robin was estimated to incidentally ingest 5.9E-04 kg/day of dry soil.

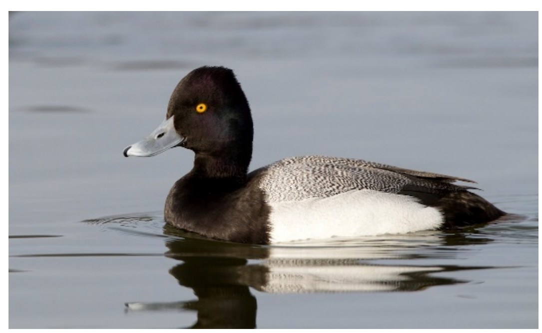
6.1.3.2 Barn Swallow

The barn swallow (*Hirundo rustica*) is a long-distance migrant moving between its breeding range in North America and overwintering range in Central and South America (Brown & Brown, 2019). Breeding habitats include open areas (e.g., fields, meadows, wetlands) for foraging, a nest site that includes a vertical or horizontal substrate with some type of roof or ceiling, and a body of water that provides mud for nest building (Brown & Brown, 2019). Barn swallows are not territorial while foraging. Foraging ranges vary from 0.8 to 4.5 km^2 (FCSAP, 2012). An average sized barn swallow weighs 0.02 kg (FCSAP, 2012). The barn swallow's diet consists primarily of aerial insects year-round. Seeds may also be consumed to a lesser extent. Grit or small pebbles are often consumed to aid digestion of insects and possibly also for calcium (Brown & Brown, 2019). Barn swallows consume approximately 0.26 kg of dry weight food (or 1.6 kg wet weight food), per kg body weight, per day and 0.22 L of water, per kg body weight, per day (FCSAP, 2012). For the present assessment, the barn swallow's diet was assumed to be 1% terrestrial plants and 99% terrestrial invertebrates. Based on its consumption of these foods, the barn swallow is estimated to incidentally ingest approximately 9.6E-05 kg/day of dry soil.

6.1.3.3 Common Loon

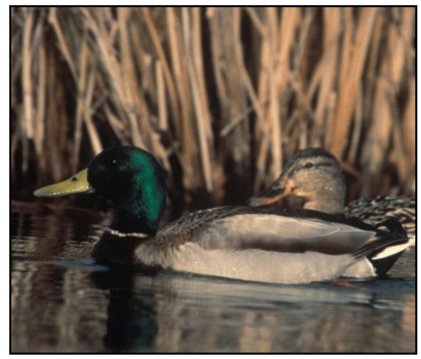
The common loon (*Gavia immer*) lives in freshwater habitats of North America. It is a medium-distance migrant. Most of the loon population shifts from freshwater inland breeding locations to coastal marine wintering locations, although some remain at inland freshwater sites throughout winter. Fall migration generally begins in September and October and by late November most migrants have arrived in their wintering areas (Evers et al., 2010). The common loon prefers lakes larger than 0.24 km^2 with clear water, an abundance of small fish, numerous small islands and an irregular shoreline that creates coves. However, it can use a wide variety of freshwater aquatic habitats, even when water level fluctuations vary regularly (Evers et al., 2010). The loon's foraging range varies from 0.04 to 0.6 km^2 (FCSAP, 2012). Loons are visual predators, preferring clear waters of littoral zones and tend to avoid foraging in deeper parts of lakes. They generally forage in relatively shallow areas (< 5 m in depth) and within 50 to 150 m of the shoreline. An average sized loon weighs 5.3 kg (FCSAP, 2012). Loons primarily eat fish, preferring prey species size classes in the range of 10 to 15 cm (e.g., perch, chubs, sucker and salmonid species). Fish larger than 30 cm (e.g., northern pike, chain pickerel and lake trout) may also be consumed (Evers et al., 2010). The common loon consumes approximately 0.19 kg of wet weight food, per kg body weight, per day and 0.034 L of water, per kg body weight, per day (FCSAP, 2012). For the present assessment, the loon's diet was assumed to be 10% benthic invertebrates and 90% fish. Based on its consumption of these foods, the loon is estimated to incidentally ingest 5.0E-03 kg/day of dry sediment.

6.1.3.4 Lesser Scaup



The lesser scaup (*Aythya affinis*) is one of the most abundant and widespread diving ducks in North American. The lesser scaup is a late fall migrant, one of the last waterfowl to leave an area at freeze-up (Anteau et al., 2014). They winter along coastal areas in the southern states and into Mexico. The core nesting habitats of the lesser scaup are in boreal forests and parklands. Their primary brood habitat is characterized by permanent wetlands dominated by emergent vegetation. Females nest in late May through June and build nests on the ground near or over water, as well as in uplands (US EPA, 1993b). The average size of their home range is 0.9 km^2 (US EPA, 1993b), while their foraging range varies from 0.1 to 17.1 km^2 (FCSAP, 2012). An average sized lesser scaup weighs 0.7 kg (FCSAP, 2012). During spring and summer, lesser scaup forage in the open-water zone of shallow wetlands and lakes (generally <3 m deep). Lesser scaup are mainly carnivorous, consuming mostly aquatic invertebrates (e.g., crustaceans, insects, molluscs, snails, polychaetes). Seeds and vegetative parts of aquatic plants may also be part of the diet in certain areas (Anteau et al., 2014). The lesser scaup consumes approximately 0.07 kg of dry weight food (or 0.29 kg wet weight food), per kg body weight, per day and 0.066 L of water, per kg body weight, per day (FCSAP, 2012). For the present assessment, the lesser scaup's diet was assumed to be 10% aquatic plants and 90% benthic invertebrates. Based on its consumption of these foods, the lesser scaup was estimated to incidentally ingest 9.3E-04 kg/day of dry sediment.

6.1.3.5 Mallard



The mallard (*Anas platyrhynchos*) is the most abundant dabbling duck species in North America. Most mallard populations in North America are sedentary, undergoing only short to medium-distance migrations during winter (Drilling et al., 2018). Their preferred foraging habitats are natural bottomland wetlands and rivers with water depths of 0.2 to 0.4 m. Their nesting habitat consists of dense grassy vegetation that provides concealment from predators. Their home ranges vary from 5.4 to 6.2 km^2 (US EPA, 1993b), while their foraging range varies from 0.09 to 2.4 km^2 (FCSAP, 2012). An average sized mallard weighs approximately 1.2 kg (FCSAP, 2012). The mallard feeds primarily on aquatic invertebrates during the breeding season and on aquatic and terrestrial plants during the non-breeding season (CWS & CWF, 1996). The mallard consumes approximately 0.05 kg of dry weight food (or 0.31 kg wet weight food), per kg body weight, per day and 0.056 L of water, per kg body weight, per day (FCSAP, 2012). For the present assessment, the mallards' diet was assumed to be 5% terrestrial plants, 5% terrestrial invertebrates, 50% aquatic plants and 40% benthic invertebrates. Based on its consumption of these foods, the mallard was estimated to incidentally ingest 1.9E-04 kg/day of dry soil and 2.0E-03 kg/day of dry sediment.

6.1.3.6 Red-tailed Hawk

The red-tailed hawk (*Buteo jamaicensis*) is the most common and widespread hawk in North America. It is typically found in open areas with scattered, elevated perches in diverse habitats including scrub deserts, plains and montane grasslands, agricultural fields, pastures, urban parks, patchy coniferous and deciduous woodlands. The red-tailed hawk makes diurnal, short- to intermediate distance migrations (<1500 km) (Preston & Beane, 2009). Northern populations of the red-tailed hawk are migratory, while populations from southern Canada may be year-round residents (US EPA, 1993b). Home range size can vary from 2 to >15 km^2, depending on the habitat (US EPA 1993b; Stout et al., 2006). The area of their foraging range varies from 0.2 to 50 km^2 (FCSAP, 2012). An average sized red-tailed hawk weighs approximately 1.1 kg (FCSAP, 2012). Red-tailed hawks generally hunt from an elevated perch, foraging primarily on small rodents such as mice, voles, shrews, rabbits, and squirrels, as well as birds and reptiles (US EPA, 1993b). They consume approximately 0.1 kg of wet weight food, per kg body weight, per day and 0.06 L of water, per kg body weight, per day (FCSAP, 2012). For the present assessment, the red-tailed hawk's diet was assumed to be 100% terrestrial prey items. Based on its consumption of these foods, the red-tailed hawk was estimated to incidentally ingest approximately 0.70 g/day of dry soil.

6.1.3.7 Spotted Sandpiper

The spotted sandpiper (*Actitis macularius*) is one of the most widespread shorebirds in North America. It is found east to west across the continent and north to south from the southern edge of the Arctic to the southern states. Spotted sandpipers are considered intermediate- to long-distance migrants. In the winter, they migrate to the southern United States and South America (Reed et al., 2013). The spotted sandpiper prefers open water for bathing and drinking, semi-open habitat for nesting and dense vegetation along the edges of bodies of water for breeding (US EPA, 1993b). Their mean home range is 0.003 km² (US EPA, 1993b), while their foraging range varies from 0.0008 to 0.012 km^2 (FCSAP, 2012). In inland areas, spotted sandpipers feed along the shores of sandy ponds and streams, sometimes straying into meadows and fields. An average sized spotted sandpiper weighs 0.038 kg (FCSAP, 2012). Their diet is composed primarily of terrestrial and aquatic insects. While flying insects comprise the bulk of the diet, crustaceans, leeches, molluscs, small fish, and carrion also are eaten (US EPA, 1993b). The spotted sandpiper consumes approximately 0.18 kg of dry weight food (or 0.98 kg wet weight food), per kg body weight, per day and 0.17 L of water, per kg body weight, per day (FCSAP, 2012). For the present assessment, the spotted sandpiper's diet was assumed to be 60% terrestrial invertebrates, 5% aquatic plants, 30% benthic invertebrates and 5% fish. Based on its consumption of these foods, the spotted sandpiper is estimated to incidentally ingest 7.0E-05 kg/day of dry soil and 6.7E-05 kg/day of dry sediment.

6.1.3.8 Spruce Grouse

The spruce grouse (*Falcipennis canadensis*) is a non-migratory year-round resident species that almost exclusively inhabits coniferous forests. Spruce grouse prefer relatively young stands over more mature conifer forest. Their home range varies from 0.03 to 3.5 km^2 (USDA Forest Service, 2004). Females nest on the ground in a small depression at the base of a tree with overhanging branches that conceal the nest. Spruce Grouse sometimes gather in small flocks in autumn but become solitary by spring; some remain solitary year-round. They do not undergo long-distance movements out of their northern forest habitats but can have localized seasonal movements (short-distance migratory movements of up to 11 km) between breeding and wintering ranges (Schroeder et al., 2018). An average sized spruce grouse weighs 0.6 kg (FCSAP, 2012). Their diet consists mainly of conifer needles. Spruce grouse usually forage higher in trees, where they can access newer needles, but may also forage on the ground, eating growing tips, flowers, fruit of small plants, mushrooms, small arthropods and terrestrial snails (Schroeder et al., 2018). Their foraging range varies from 0.03 to 0.24 km^2 (FCSAP, 2012). Spruce grouse consume approximately 0.07 kg of dry weight food (or 0.46 kg wet weight food), per kg body weight, per day and 0.07 L of water, per kg body weight, per day (FCSAP, 2012). For the present assessment, the spruce grouse's diet was assumed to be 95% terrestrial plants and 5% terrestrial invertebrates. Based on its consumption of these foods, the spruce grouse is estimated to incidentally ingest approximately 8.3E-04 kg/day of dry soil.

6.1.4 Herptiles

The RAA provides suitable habitat for amphibians. The 2015/2016 amphibian baseline studies indicate that boreal chorus frogs (*Pseudacris maculate)* and wood frogs (*Lithobates sylvaticus)* are widely dispersed in well-vegetated wetlands throughout the RAA. During the peak frog breeding period in May, both species were observed using the same breeding ponds, indicating overlapping habitat preferences in the RAA. No reptile ranges overlap with the RAA; therefore, only amphibians will be assessed qualitatively in the ERA.

The wood frog was chosen to represent amphibians in the ERA because it is a FCSAP-listed receptor that is present in the RAA. The wood frog is the second most widely distributed frog in North America. Wood frogs use a variety of habitats and have a multiphasic life history (i.e., obligatory aquatic egg and tadpole phases plus terrestrial adult). Their preferred breeding habitats include ponds that have emergent vegetation, still water, and shallow, sloping shores, as well as moist grassy meadows, willow bogs, or forests with moderate to thick leaf litter (USDA, 2005). Their average foraging range is 0.25 km^2 (FCSAP, 2012). An average sized wood frog weighs 0.008 kg (FCSAP, 2012). Adult wood frogs are carnivorous, feeding primarily on arthropods such as ants, flies, beetles, spiders and to a lesser extent snails, slugs and earthworms. Tadpoles are omnivorous, feeding on algae, bacteria, and periphyton (USDA, 2005). Food and water ingestion rates for the wood frog are unknown (FCSAP, 2012).

6.1.5 Community Based Ecological Receptors

The primary exposure pathway for some flora and fauna is from direct contact with a single abiotic environmental medium (e.g., soil). Accordingly, toxicity benchmarks are commonly derived based on COPC media concentrations and the adverse environmental effects thresholds for organisms that reside/rely on those media. Additionally, these benchmarks are typically generated using toxicity data for not one, but several species that rely on that medium, and are intended to represent a COPC concentration that will be protective of most, if not all species associated with that medium. For these reasons, the following ecological receptors were evaluated in this ERA at the community level, rather than as individual species:

- Terrestrial plants
- Terresrial invertebrates
- Benthic invertebrates

- Freshwater aquatic life.

6.1.6 Species at Risk

Species at Risk (SAR) are those species designated under Schedule 1 of the federal *Species at Risk Act* (SARA). Species of Conservation Concern (SOCC) are those species listed under *The Endangered Species and Ecosystems Act* (ESEA) in Manitoba, those identified as at risk by the Committee on the Status of Endangered Wildlife in Canada (COSEWIC), or as provincially rare (Ranks S1, S2, and S3) by the Manitoba Conservation Data Centre (MB CDC) (Stantec 2020d).

The RAA overlaps the current or historical ranges of 14 SAR and four SOCC (Stantec, 2020d). There are:

- Five mammals (little brown myotis [Myotis lucifugus], northern myotis [Myotis septentrionalis], wolverine [Gulo gulo], woodland caribou [Rangifer tarandus caribou] and barren-ground caribou [*Rangifer tarandus groenlandicus*]).
- Ten birds (trumpeter swan [*Cygnus buccinator*], horned grebe *[Podiceps auratus*], yellow rail [*Coturnicops noveboracensis*], short-eared owl [*Asio flammeus*], common nighthawk [*Chordeiles minor*], olive-sided flycatcher [*Contopus cooperi*], bank swallow [*Riparia riparia*], barn swallow [*Hirundo rustica*], evening grosbeak [*Coccothraustes vespertinus*], and rusty blackbird [*Euphagus carolinus*]);
- One amphibian (northern leopard frog [*Lithobates pipiens*]); and
- Two insects (yellow-banded bumble bee [*Bombus terricola*] and transverse lady beetle [*Coccinella transversoguttata*]).

Of the five SAR/SOCC mammals with potential to occur in the RAA, three were observed during baseline surveys: little brown myotis, wolverine, and the woodland caribou (Stantec, 2020d). Field surveys confirmed the presence of little brown myotis foraging at the MacLellan region. Although not observed through field surveys, the northern myotis also has potential to inhabit the existing mine infrastructure. Wolverine were observed at three cameras trap sites and throughout the RAA during aerial track surveys. Woodland caribou were detected in the RAA in April 2019; results from the baseline remote camera survey provided a recent observation of several individuals in the RAA west of Lynn Lake, which indicates woodland caribou may occasionally occur in the RAA. Traditional ecological knowledge indicates that barren-ground caribou were hunted in the northern portion of the RAA until the early 1950s and are now harvested outside of the RAA. The occurrence of barren-ground caribou range in the RAA is considered historical (Stantec 2020d).

Of the ten bird SAR/SOCC with potential to occur within the RAA, four species (common nighthawk, olive-sided flycatcher, barn swallow and rusty blackbird) were observed during baseline surveys within the RAA. Yellow rail, short-eared owl, bank swallow, evening grosbeak, trumpeter swan, and horned grebe are not expected to regularly occur in the RAA, based on range distributions and limited occurrences in this region, as well as a lack of suitable breeding habitat (Stantec 2020d).

Though the current or historical range of northern leopard frogs overlap the RAA, they are unlikely to regularly occupy the RAA and they have not been detected in waterbodies with the potential to be affected by the Project (Stantec, 2020d).

Although there have been no incidental observations of the yellow-banded bumble bee and the transverse lady beetle during baseline field surveys, both species remains relatively common in the northern, boreal extent of its range (Stantec, 2020d). Sufficient information is not available to assess insects at the species level within the ERA. Rather these species will be assessed on a community-level as part of terrestrial invertebrates.

It is difficult in ERA to quantitatively address COPC risk to SAR/SOCC because quantitative information is often lacking on diet, inadvertent soil ingestion, water intake and toxicological reference data. To accommodate SAR in this ERA, ecological receptors found within the same class and within a similar trophic level or feeding guild were used as surrogates to assess toxicological risk from exposure to COPC (Table 6-2). The results of the ERA for those species can be applied to the SAR.

6.1.7 Ecological Receptor Locations

Potential risks to ecological receptors were assessed for the Gordon region and the MacLellan region separately. Unlike the HHRA, these two regions were not further subdivided to assess risk at specific locations. Rather, exposures within the Gordon region and the MacLellan region were assessed using a hybrid approach representative of potential upper limit exposures for each media at each region such that risk for ecological receptors (as populations, communities or individual SOCC) are derived. Where measured baseline data were available/applicable, the EPCs were based on the 95 percent (%) upper confidence limit of the mean (UCLM) or maximum concentrations. The 95% UCLMs represent reasonably expected and spatially distributed COPC exposure concentrations for ecological receptors. As such, instead of assessing potential risks to ecological receptors at a number of specific locations, both the Gordon region and the MacLellan region were conservatively assessed using upper limit exposures to represent one single assessment of overall potential ecological risks at each region.

6.1.8 Summary of Ecological Receptors

The ecological receptor profiles are summarized in Table 6-3, below. Where possible, preference was given to life history parameters for receptors as published by FCSAP in the Ecological Risk Assessment Guidance, Module 3 (FCSAP 2012). Deviations from FCSAP guidance are explained in the species profiles above.

Table 6-2 Species at Risk and Surrogate Ecological Receptors used in ERA

Common Name of Species at Risk	Scientific Name of Species at Risk	Common Name of Ecological Receptor used as Surrogate in ERA	Scientific Name of Ecological Receptor used as Surrogate in ERA
Mammals			
Little brown myotis	*Myotis lucifugus*	Common masked shrew	*Sorex cinereus*
Northern myotis	*Myotis septentrionalis*	Common masked shrew	*Sorex cinereus*
Wolverine	*Gulo gulo*	Short-tailed weasel	*Mustela erminea*
Woodland caribou	*Rangifer tarandus caribou*	Woodland caribou	*Rangifer tarandus caribou*
Birds			
Barn swallow	*Hirundo rustica*	Barn swallow	*Hirundo rustica*
Common nighthawk	*Chordeiles minor*	Barn swallow	*Hirundo rustica*
Olive-sided flycatcher	*Contopus cooperi*	Barn swallow/American robin	*Hirundo rustica* / *Turdus migratorius*
Rusty blackbird	*Euphagus carolinus*	Barn swallow/American robin	*Hirundo rustica* / *Turdus migratorius*
Terrestrial Invertebrates			
Yellow-banded bumble bee	*Bombus terricola*	Terrestrial invertebrate community	Terrestrial invertebrate community
Transverse lady beetle	*Coccinella transversoguttata*	Terrestrial invertebrate community	Terrestrial invertebrate community

Table 6-3 Summary of Ecological Receptor Profiles

Receptor	Average Weight (kg)	Foraging Range (km^2)	Food Ingestion (kg wet weight food/kg BW/day)	Water Ingestion (L/kg BW/day)	Soil/ Sediment Ingestion (kg dry weight/day)	Diet (Specific to Assessment)
Mammals						
American Beaver	24	0.08 to 0.18	0.022	0.072	3.9E-03 (soil) 6.2E-03 (sediment)	55% Terrestrial plants 45% Aquatic plants
American Mink	0.82	0.06 to 16.3	0.14	0.037	1.8E-04 (soil) 4.3E-04 (sediment)	25% Terrestrial prey 10% Benthic invertebrates 65% Freshwater fish
Black Bear	68	3.0 to 1147	0.19	0.064	4.1E-02 (soil) 3.2E-03 (sediment)	80% Terrestrial plants 5% Terrestrial invertebrates 10% Terrestrial prey 5% Freshwater fish
Common Masked Shrew	0.0041	0.006	2.1	0.17	2.8E-05 (soil)	5% Terrestrial plants 95% Terrestrial invertebrates
Deer Mouse	0.022	0.0001 to 0.004	0.27	0.19	1.8E-05 (soil)	50% Terrestrial plants 50% Terrestrial invertebrates
Meadow Vole	0.035	0.00007 to 0.0035	0.33	0.21	4.1E-05 (soil)	100% Terrestrial plants
Moose	400	4.6 to 262	0.13	0.054	1.2E-01 (soil) 2.6E-02 (sediment)	80% Terrestrial plants 20% Aquatic plants
Muskrat	1.0	0.0003 to 0.008	0.46	0.099	1.4E-03 (sediment)	80% Aquatic plants 15% Benthic invertebrates 5% Freshwater fish
Northern River Otter	7.5	9.0 to 231	0.12	0.08	2.9E-04 (soil) 4.2E-03 (sediment)	5% Terrestrial prey 15% Benthic invertebrates 80% Freshwater fish
Short-tailed Weasel	0.089	0.01 to 0.87	0.33	0.13	1.9E-04 (soil)	100% Terrestrial prey
Snowshoe Hare	1.3	0.02 to 0.10	0.40	0.096	4.9E-03 (soil)	100% Terrestrial plants

Table 6-3 Summary of Ecological Receptor Profiles

Receptor	Average Weight (kg)	Foraging Range (km^2)	Food Ingestion (kg wet weight food/kg BW/day)	Water Ingestion (L/kg BW/day)	Soil/ Sediment Ingestion (kg dry weight/day)	Diet (Specific to Assessment)
Woodland Caribou	160	710	0.05	0.059	1.7E-01 (soil)	100% Terrestrial plants
Birds						
American Robin	0.079	0.007 to 0.28	1.2	0.14	5.9E-04 (soil)	60% Terrestrial plants 40% Terrestrial invertebrates
Barn Swallow	0.019	0.8 to 4.5	1.6	0.22	9.6E-05 (soil)	1% Terrestrial plants 99% Terrestrial invertebrates
Common Loon	5.3	0.04 to 0.60	0.19	0.034	5.0E-03 (sediment)	10% Benthic invertebrates 90% Freshwater fish
Lesser Scaup	0.71	0.10 to 17	0.29	0.066	9.3E-04 (sediment)	10% Aquatic plants 90% Benthic Invertebrates
Mallard	1.2	0.09 to 2.4	0.31	0.056	1.9E-04 (soil) 2.0E-03 (sediment)	5% Terrestrial plants 5% Terrestrial invertebrates 50% Aquatic plants 40% Benthic invertebrates
Red-tailed Hawk	1.1	0.2 to 50	0.10	0.057	7.0E-04 (soil)	100% Terrestrial prey
Spotted Sandpiper	0.038	0.0008 to 0.012	0.98	0.17	7.0E-05 (soil) 6.7E-05 (sediment)	60% Terrestrial invertebrates 5% Aquatic plants 30% Benthic invertebrates 5% Freshwater fish
Spruce Grouse	0.60	0.03 to 0.24	0.46	0.070	8.3E-04 (soil)	95% Terrestrial plants 5% Terrestrial invertebrates
Amphibians						
Wood Frog*	0.008	0.25	n/a	n/a	n/a	100% Terrestrial invertebrates

NOTES:
n/a- information is not available
* There are not sufficient exposure and toxicity data to evaluate amphibians quantitatively, thus a qualitative assessment will be conducted.

Table 6-4 Rationale for Exposure Pathway Inclusion in the ERA

Exposure Pathway	Carried Forward in the ERA	Rationale
Direct Exposure from Air	Yes	Some COPC (e.g., NO_2 and SO_2) may be directly absorbed from the air by terrestrial plants.
Soil Ingestion	Yes	Soil ingestion is an important dietary component for many ecological receptors including herbivores and ungulates. Direct ingestion of soil provides essential minerals such as sodium, calcium, iron and zinc to supplement diets that are naturally low in mineral content. Incidental soil ingestion may occur through the ingestion of food items. Examples include soil bound to browse, forage and root vegetation when consumed by herbivores; or soil bound to prey items on the ground. Incidental soil ingestion may also occur through grooming activities. Therefore, the ingestion of soil constitutes a potential source of exposure to mammalian and avian receptors.
Soil Contact	Yes	Direct contact with soil is the primary exposure pathway for soil invertebrates and plants. Direct (dermal) contact with soil could be a potential exposure pathway for mammals and birds. However, it is not expected to represent a major source of exposure for most mammalian and avian receptors because fur and feathers will significantly reduce soil contact with skin (Sample and Suter 1994). Soil adhering to fur and feathers may be ingested during grooming activity which is included in the incidental soil ingestion estimates.
Inhalation	No	Ecological receptors may be exposed to COPC through the inhalation of dust. However, this exposure pathway is included with soil ingestion since it was assumed that the majority of inhaled particulates will be caught in the mucus membrane, coughed up and swallowed by the animal. With respect to potential effects on the respiratory system, there is insufficient toxicological dose-response information available to properly evaluate the potential effects associated with inhalation exposures to COPC for ecological receptors and the biological mechanisms of action associated with inhalation exposures often differ from those associated with ingestion exposures. Thus, using exposure benchmarks derived for ingestion exposures to assess potential risks associated with inhalation exposures is often incorrect. Therefore, inhalation is not considered further in the ERA.
Ingestion of Terrestrial Foods	Yes	The consumption of terrestrial plants, terrestrial invertebrates and terrestrial prey can be a source of exposure for mammals and birds.
Surface Water Ingestion	Yes	The ingestion of surface water containing COPC can be an exposure pathway for mammals and birds.
Ingestion of Aquatic Foods	Yes	The ingestion of aquatic plants, invertebrates and fish can be an exposure pathway for mammals and birds.
Direct Contact with Surface Water	Yes	Direct contact with surface water is an exposure pathway to aquatic receptors such as fish, aquatic plants and benthic invertebrates. Exposure to COPC from direct contact with water was assumed to be a minor exposure pathway relative to direct ingestion of water and ingestion of foods (e.g., fish) from the aquatic environment, both of which have been included in the ERA.

Table 6-4 Rationale for Exposure Pathway Inclusion in the ERA

Exposure Pathway	Carried Forward in the ERA	Rationale
Ingestion of Sediment	Yes	Ecological receptors that consume aquatic plants and benthic invertebrates may also ingest sediments incidentally. Other activities such as grooming and constructing nests or dens may also result in incidental sediment ingestion. Therefore, this exposure pathway is considered in the ERA.
Ingestion of Benthic Aquatic Foods	Yes	The diets of some mammalian and avian receptors include a proportion of benthic invertebrates. Therefore, this exposure pathway is considered in the ERA.
Direct Contact with Sediment	Yes	Benthic invertebrates live in or are associated with sediments for most of their lifespan. Therefore, direct contact with sediments is the primary exposure pathway for benthic invertebrates. For mammalian and avian receptors, direct contact with sediment is considered to be minor exposure pathway relative to the exposures from ingestion of sediment benthic foods.

6.1.9 Conceptual Site Model

The objective of the Problem Formulation stage is to develop a CSM that will aid in subsequent stages of quantitative analyses. The CSM illustrates the pathways by which ecological receptors could be exposed to COPC released into the environment from the Project. Chemical transport and exposure pathways are used to describe the movement of COPC from a release point or source (e.g., dust released by Project activities and treated effluent discharge or other releases to watercourses) to the point where an ecological receptor may come into contact with the COPC (e.g., direct exposure or ingestion). The exposure pathway screening process incorporates information about the Project-related COPC emissions, activities in the area, receptor characteristics and the exposure pathways. The chemical exposure pathways considered in the ERA, and the rationale for the exposure pathway being included or excluded in the assessment, is found in Table 6-4 above.

The CSM for the ERA represents the interactions between the receptors and the COPC, via the identified exposure pathways. The relevant exposure pathways are designated by arrows from the source media leading to the receptor by various exposure pathways (i.e., direct exposure or ingestion). Pathway exposure boxes marked with an "✓" indicate pathways that have been quantitatively evaluated in the ERA, while those marked with an "o" indicate pathways that have been qualitatively evaluated.

SOURCE → RECEPTORS

✔ Pathway quantitatively assessed in ERA
O Pathway qualitatively assessed in ERA
--- Pathway not applicable

6.1.10 Protection Goals and Acceptable Effect Levels

Changes to individual health do not necessarily equate to eventual changes in population health over time. The goal of an ERA is typically to identify potential risks to ecological receptors at the population/community level rather than at the individual level, with the notable exception being species protected under federal or provincial legislation (e.g., ESEA in Manitoba and the federal SARA). As mentioned in Section 6.1.6, SOCC have been reported the RAA overlaps the current or historical ranges of 16 SOCC. Consequently, for the purpose of this ERA, the primary assessment endpoints were the protection of populations and communities for standard species (i.e., not species at risk) and the protection of individuals for species at risk (i.e., SOCC), based on predicted changes to growth, reproduction, or survival (CCME 2020).

6.2 EXPOSURE ASSESSMENT

The purpose of the exposure assessment is to quantify an ecological receptor's total exposure to a COPC. The total exposure to a COPC is calculated as the sum of exposures (i.e., EPC) from the contributing exposure pathways identified in the CSM and Table 6-4 (e.g., soil ingestion). The determination of EPCs used in the ERA to predict risk resulting from the Baseline Case and Future Case were previously discussed in Section 4.0.

6.2.1 Calculation of Average Daily Dose

To conduct a quantitative risk assessment for birds and mammals, it is necessary to estimate the rate of exposure to a COPC on a mg/kg-day basis (referred to as the average daily dose or ADD). The exposure assessment estimates the ADD of each COPC to a receptor based on the sum of the contribution from each complete exposure pathway illustrated in the CSM and described in Table 6-4. It is conservatively assumed in this ERA that the ingested COPC contained in food, water, soil and sediment will be completely absorbed. The generalized formula to estimate ADD is:

$$\boldsymbol{ADD_i = IF \times AF \times EPC_i} \quad \text{Equation 6-1}$$

where:

- ADD_i = Average daily dose for COPC "i" (mg COPC/kg body weight/day);
- IF = Intake factor (kg medium/kg body weight/day);
- AF = Absorption factor for COPC (unitless; assumed to be 1 or 100% absorption); and
- EPC_i = Exposure point concentration for COPC "i" (mg COPC/kg medium).

The IF is calculated based on the ingestion rate of each media type (i.e., ingestion of food, water, soil and sediment) for each ecological receptor, the fraction of time each receptor spends at the site (f_{SITE}), and the receptor's body weight (BW). The f_{SITE} is conservatively set at 1.0 for this ERA, which assumes that receptors spend 100% of their time within the LAA, and a function of the receptor's body weight (BW) in kilograms, as follows:

Equation 6-2

$$IF = \frac{(IR \times f_{site})}{BW}$$

The generalized formula for ADD applies to a single exposure pathway (e.g., ingestion of water or small mammals). The total ADD that is used to compare against the TRV is the sum of the ADDs for the relevant exposure pathways. The results of the calculation of the ADD for each ecological receptor and COPC are provided in Appendix G.

6.3 TOXICITY ASSESSMENT

The objective of the Toxicity Assessment is to identify the potential adverse effects associated with chronic exposure of ecological receptors to each COPC. The amount of a substance that can be tolerated, below which adverse effects are not expected to be observed in a population, is referred to as the toxicity reference value, or TRV. For community receptors screening benchmarks are used as markers of toxicity, below which adverse effects are not expected to be observed at a community level.

The TRVs and screening benchmarks for each COPC applicable to ecological receptors are presented in Appendix G. Numerous literature sources were reviewed to obtain the most applicable TRV/benchmarks for ecological receptors including, but not limited to:

- CCME Environmental Quality Guidelines (CCME 1999f, g and updates)
- Manitoba Water Quality Standards, Objectives and Guidelines (MWQSOG 2011)
- Guidance for Developing Ecological Soil Screening Levels (US EPA 2007 (Eco-SSL))
- Contaminant-Specific Ecological Soil Screening Levels Documents (US EPA various dates)
- Oak Ridge National Laboratory (ORNL various dates)
- National Institute for Public Health and the Environment, The Netherlands
- primary scientific literature

6.3.1 Mammals and Birds

For mammals and birds, TRVs for this ERA were mainly derived using the US EPA Guidance for Developing Ecological Soil Screening Levels (2007) and Ecological Soil Screening Levels Documents specific to each metal (US EPA various dates), although primary scientific literature was also consulted. TRVs used in this ERA were based on dose response studies, typically conducted with laboratory animals, where the lowest observed adverse effects level (LOAEL) or no observed adverse effects level (NOAEL) has been quantified. The preferred toxicity measure used in this ERA is the LOAEL; however, in the absence of a suitable value, NOAEL-based TRVs were used.

As noted in Section 6.1.10, the focus of an ERA is to assess the risk for receptors at the population level. The application of TRVs derived from LOAELs is preferred in the calculation of risk. LOAELs are based on long-term growth or survival, or sub-lethal reproductive outcomes determined from chronic exposure studies. As such, these endpoints are relevant to the maintenance of wildlife populations. This is in contrast to human toxicology and human health risk assessment, where protection of individuals is of paramount concern. An exception to this occurs in ERA when federally or provincially designated SAR or SOCC are evaluated. To afford these species an appropriate level of protection in the ERA, TRVs that are NOAEL based are preferred; if NOAELs are not available then a sensitive species factor (a numerical value of 3) is applied to LOAELs.

In addition to the sensitive species factor, other uncertainty factors were applied as deemed necessary. If the TRV was based on an acute lethal dose (LD_{50}, the amount of an ingested substance that kills 50 percent of a test sample), then it was adjusted by a factor of 100 to make it comparable to a chronic LOAEL. A subchronic LOAEL or NOAEL was adjusted by 3 to make it comparable to a chronic LOAEL. A body mass scaling factor was also applied to extrapolate toxicity data between species with different body masses. The application of this factor only applies when TRVs were based on individual studies (rather than geometric means from numerous animals) and only when the test organism was smaller than the ecological receptor. Body-mass scaling or “dose-scaling” (as it is often referred) provides a more conservative estimate of the TRV when the toxic response observed for small animals is used to extrapolate the expected response for larger animals (Knopper et al. 2009). This was the only circumstance under which it was applied. Therefore, the primary uncertainty was that the assessment would potentially overestimate the health risks to the ecological receptors. The uncertainty factor scheme outlined here is based on guidance provided by Ohio EPA (2003, 2008), US EPA (2002), Sample and Arenal (1999) and the professional judgement of the Study Team.

The scaling process itself is described by Sample et al. (1996). If a toxicity value for a given test species (At), an allometric scaling factor (b), and the body weights of the test species (BWt) and a selected wildlife species (BWw) are known, then the unknown toxicity value for a particular wildlife species (Aw) may be estimated using the following equation:

Equation 6-3

$$\mathrm{Aw} = \mathrm{At} \times \left(\frac{\mathrm{BWt}}{\mathrm{BWw}}\right)^{(1-\mathrm{b})}$$

For both birds and mammals, (b) was assigned a value of 0.75.

6.3.2 Community Receptors

For community receptors, regulatory benchmarks protective of vegetation, soil invertebrates, benthic invertebrates and freshwater aquatic life were used in the ERA when available. Information from the primary literature was used when regulatory benchmarks were not available for a specific COPC and community receptor. Regulatory benchmarks are based on toxicity studies for multiple species; to establish the adverse environmental effects thresholds for organisms that reside or rely on these media. They are intended to represent a COPC concentration that will be protective of most species associated with that medium.

6.3.2.1 Terrestrial Plants and Soil Invertebrates

When selecting soil screening benchmarks for the terrestrial plant and soil invertebrate community, priority was given to CCME Soil Quality Guidelines for the protection of Environmental Health (SQG_E) for the most sensitive land use, agricultural. The SQGs for agricultural land use were developed to ensure that the soil is capable of sustaining soil-dependent species and considers direct soil contact by microbes (and their effect on nutrient cycling), soil invertebrates, crops and plants. Manitoba Sustainable Development accepts the use of criteria from the CCME as well as from other sources and jurisdictions (Government of Manitoba 2020). In the event that guidelines were not available from CCME (i.e., for manganese), the US EPA Ecological Soil Screening Levels (Eco-SSL) were used. The soil screening benchmarks for each COPC are summarized in Appendix G.

6.3.2.2 Benthic Invertebrates

When selecting sediment screening benchmarks for the benthic invertebrate community, priority was given to CCME Sediment Quality Guidelines for the Protection of Aquatic Life, Freshwater Probable Effect Level (PEL), followed by MWQSOG (2011) for Sediment. In the event that guidelines were not available from these two sources, sediment screening benchmarks were based on guidelines from Verbruggen *et al.* (2001) and van Vlaardingen *et al.* (2005) for the National Institute for Public Health and the Environment, The Netherlands (hereafter, RIVM).

The RIVM sediment screening benchmarks are based on the ecotoxicological serious risk concentration (SRC_{eco}) which they defined as the “concentration of a substance in the soil, sediment or groundwater at which functions in these compartments will be seriously affected or are threatened to be negatively affected. This is assumed to occur when 50% of the species and/or 50% of the microbial and enzymatic processes are possibly affected”. Therefore, the SRC_{eco} is similar to the PEL as defined in the CCME sediment quality guidelines (i.e., it is expected that adverse effects occur more than half the time at concentrations above the PEL). However, recognizing the potential uncertainty associated with the SRC_{eco} values for these elements, the SRC_{eco} values were modified by dividing them by an additional factor of 10 before using them as screening benchmarks.

The sediment screening benchmarks for each COPC are summarized in Appendix G.

6.3.2.3 Freshwater Aquatic Life

When selecting surface water screening benchmarks for the freshwater aquatic community, priority was given to CCME Water Quality Guidelines for the Protection of Aquatic Life (CWQG-FAL). The CWQG-FALs are intended to be protective of all forms of aquatic life and all aspects of the aquatic life cycle during acute and/or chronic exposure regimes (i.e., short-term or long-term exposure). In the absence of a CWQG-FAL, the most stringent of the Tier II and III MWQSOG (2011) for the protection of aquatic life were used. Priority was given to guidelines based on long-term exposure. In the event that guidelines were not available from these two sources, freshwater aquatic life benchmarks were obtained from the US EPA and RIVM.

The water screening benchmarks for each COPC are summarized in Appendix G.

6.4 RISK CHARACTERIZATION

The purpose of the Risk Characterization step in ERA is to evaluate potential adverse effects of identified COPC by combining information from the Exposure and Toxicity Assessments. For the assessment of mammalian and avian receptors, the potential for adverse effects is quantified by comparing the dose of a substance that can be tolerated on a daily basis, or below which adverse environmental effects are not expected (i.e., TRV), to the expected daily dose, which is the amount of a COPC an organism is expected to be exposed to on a daily basis (i.e., the ADD). The quotient of the two is unitless and referred to as a risk quotient (RQ). The magnitude by which RQ values differ from parity (i.e., TRV = ADD, target RQ of 1.0) is used to make inferences about the magnitude of ecological risks. For the assessment of potential risk to community-based receptors, a screening ratio (SR) is calculated rather than an RQ. The SR is defined as the EPC of the COPC in the associated environmental media (e.g., soil) divided by a toxicological benchmark for the community receptors (e.g., terrestrial plants).

When the change in RQ or SR between Baseline Case and Future Case is less than 1.0, the probability of unacceptable levels of risk to ecological receptors at the population level, as a result of the Project, is expected to be negligible. When the change in RQ or SR between Baseline Case and Future Case is greater than 1.0, there is a potential (but not a certainty) that adverse effects to the ecological receptor as a result of the Project may exist. In these cases, additional analysis and considerations are required including a review of the assumptions applied in the assessment to provide a more accurate prediction of ecological risk. If it is ultimately determined that the RQ or SR indicates an unacceptable ecological health risk, mitigation or remediation activities may be recommended to reduce potential risks to ecological receptors.

6.4.1 Ecological Risk Characterization Results

6.4.1.1 Mammals and Birds

The RQs for mammalian and avian receptors exposed to COPC throughout the LAA are summarized in Table 6-5 through Table 6-29. RQs greater than 1.0 are noted in bold text. The detailed RQ contribution from each exposure pathway for each ecological receptor species are provided in Appendix G.

Changes in calculated RQs between the Baseline Case and the Future Cases were less than 1.0 for all COPC and all ecological receptors VECs assessed at both the Gordon region and the MacLellan region. As such, predicted Project-related increases in risks between Baseline Case and Future Case for mammals and birds are considered negligible.

Even when considering the Baseline Case and the Future Case separately (i.e., not considering the changes in RQs between the two cases), most of the calculated RQs for COPC and ecological receptors assessed were less than 1.0. The following exceptions were however noted.

For the Gordon region, RQs higher than 1.0 were calculated for both the Baseline Case and the Future Case for copper, nickel, molybdenum, selenium, vanadium and/or zinc for several ecological receptors. In most of these cases, the Project-related contribution to the RQ is negligible (generally less than 1%). Only one noticeable increase was noted at the Gordon region. For the northern river otter exposed to selenium (Table 6-14) an RQ of 0.74 for the Baseline Case increased to an RQ of 1.1 for the Future Case. However, the Future Case RQ of 1.1 is only marginally above the target RQ of 1.0. Therefore, calculated Project-related increases in the risks for these ecological receptors at the Gordon region due to exposure to metals assessed are considered negligible.

For the MacLellan region, RQs higher than 1.0 were calculated for both the Baseline Case and the Future Case for chromium, copper, nickel, selenium, vanadium and/or zinc for several ecological receptors. In most cases, the Project-related contribution to the RQ is negligible (generally less than 1%). Similar to the Gordon region, only one noticeable increase was noted at the MacLellan region. For the northern river otter exposed to selenium (Table 6-14) an RQ of 0.90 for the Baseline Case increased to an RQ of 1.1 for the Future Case. However, the Future Case RQ of 1.1 is only marginally above the target RQ of 1.0. Therefore, Project-related increases in the risks for these ecological receptors at the MacLellan region due to exposure to these metals are considered negligible.

RQs higher than 10 were calculated for nickel at the MacLellan region under the Baseline and Future Case for three receptors: masked shrew (Table 6-8) and the little brown myotis and the northern myotis SAR (Table 6-9). However, the predicted RQ exceedances for nickel for these receptors of the threshold of 1.0 exist under the Baseline Case, and the Project-related contribution to the Future Case is negligible (i.e., the percent increase in RQ between Baseline Case and Future Case is less than 1%). For these ecological receptors, the terrestrial invertebrate ingestion pathway represents a substantial contribution to the overall RQ (more than 95%). As measured data were not available for terrestrial invertebrates, COPC concentrations in terrestrial invertebrates were estimated by applying soil-to-terrestrial invertebrate uptake factors obtained from Sample et al., (1998a). These uptake factors are predictive of COPC concentrations in earthworms based on soil EPCs. Due to the differences in habitat and diet of invertebrate taxa, some soil invertebrate species are more likely to accumulate metals in greater amount than others (Heikens et al., 2001). In general, the most important route for assimilation of metals by soil invertebrates is through ingestion (Efroymson et al., 1997b). Earthworms are geophagus organisms that ingest a large amount of soil during feeding and therefore, are more highly exposed to soil contaminants than other species which have less intensive contact with contaminated soil (Gall et al., 2015). Moreover, earthworms can constitute a large fraction of the biomass of soil-dwelling invertebrates, are important in the formation of soils, and constitute a significant fraction of the diet of some vertebrates (Nahmani et al., 2007). As such, earthworms serve as model organisms in toxicology studies and are considered to be representative of soil invertebrates in ERAs. The common masked shrew may consume earthworms; however, the calculated increase in metal concentrations in earthworms as a result of Project activities is negligible, therefore the corresponding changes in exposure between Baseline Case and Future Case are also expected to be negligible. The little brown myotis and northern myotis generally capture insects in flight. They feed on a variety of small, flying insects such as moths, flies, mosquitoes, mayflies, caddisflies, beetles, and midges; many of which have aquatic life stages (COSEWIC, 2013; Pennsylvania State University 2002). Aerial insects have minimal contact with soil and are thus not expected to be highly exposed to soil COPC. Therefore, exposure estimates for the insectivorous bat based on consumption of earthworms likely overestimate their exposures. Given that the modelled COPC concentrations in terrestrial invertebrates are based on earthworms, and that bats do not actually consume earthworms, it expected that the exposure that a bat would receive from consuming aerial invertebrates at the MacLellan region would be much less than predicted based on earthworm ingestion and thus unacceptable risks to bats due to exposure to nickel are also not expected.

6.4.1.2 Plant and Terrestrial Invertebrate Communities

Screening ratios for terrestrial plant and invertebrate communities exposed to COPC in soil were calculated by comparing soil EPCs to the applicable soil quality guidelines outlined in Section 6.3.2. The SRs for terrestrial plants and invertebrates, for the Baseline Case (based on measured baseline soil data) and the Future Case (based on predicted deposition) are summarized in Table 6-34. The SRs for terrestrial plant and invertebrate communities were below 1.0 for both the Baseline Case and the Future Case for COPC assessed with the exception of molybdenum at the Gordon region and copper at the MacLellan region.

Due to the very small contribution of dust deposition to the Future Case concentrations of COPC, there was no substantive difference in risks to terrestrial plants and invertebrates exposed to molybdenum and copper in soil between the Baseline Case and the Future Case. The identified exceedances of the target benchmark of 1.0 are related to pre-existing baseline metal concentrations in the soil, and the Project-related contribution to these environmental effects is negligible (i.e., <1%). As such, unacceptable risks to terrestrial plants and invertebrates as a result of project-related contributions of molybdenum and copper to soil are not expected. Toxicity benchmarks were not identified for strontium, therefore a SR could not be calculated. However, inferences about the magnitude of risk for terrestrial plants and invertebrates from exposure to strontium in the soil as a result of the project, can be made by looking at the difference in the strontium concentration in soil between Baseline Case and Future Case. The increase in the concentration of strontium in soil as a result of Project-related activities is negligible (<1%). As such, baseline risks and future risks are expected to remain essentially unchanged; thus, unacceptable risks to terrestrial plants and invertebrates as a result of project-related contributions of strontium to soil are not expected.

Screening ratios for terrestrial plant communities exposed to NO_2 and SO_2 in air were calculated by comparing the maximum annual average air EPCs to the applicable CAAQs meant to be protective of environmental (and human) health. The SRs for terrestrial plant communities were below 1.0 for both the Baseline Case and the Future Case at the Gordon and MacLellan regions (Table 6-35). As such, unacceptable risks to terrestrial plants from exposure to NO_2 and SO_2 in air are not expected.

6.4.1.3 Benthic Invertebrate Communities

Screening ratios for benthic invertebrate communities exposed to COPC in sediment were calculated by comparing sediment concentrations to sediment quality guidelines as outlined in **Section 6.3.2**. The SR for the Baseline Case and the Future Case are provided in **Table 6-36**. The SRs for benthic invertebrate communities were below 1.0 for both the Baseline Case and the Future Case for COPC assessed, with the exception of chromium and nickel at the MacLellan region. The predicted SR exceedances for chromium and nickel for these receptors were identified for the Baseline Case, and the Project-related contributions to the Future Case are negligible (i.e., percent increases in SR between Baseline Case and Future Case are less than 1% for chromium and less than 2% for nickel). As such, unacceptable risks to benthic invertebrates as a result of project-related contributions of chromium and nickel to sediment are not expected.

Toxicity benchmarks were not identified for manganese, silver, strontium, thallium and uranium in sediment; therefore, SRs could not be calculated. However, inferences about the magnitude of risk for benthic invertebrate communities from exposure to these COPC in the sediment as a result of the project, can be made by looking at the differences in the sediment concentrations between Baseline Case and Future Case.

The increase in the concentration of silver in sediment as a result of Project-related activities at both the Gordon and MacLellan regions is expected to be negligible (<1%). As such, unacceptable risks to benthic invertebrate communities as a result of project-related contributions of silver to sediment are not expected.

The increase in the concentration of manganese in sediment as a result of Project-related activities is 5% for the Gordon region and 2% for the MacLellan region. Manganese is a naturally occurring element that is ubiquitous in the environment. It is also an essential micronutrient for biota (MOEE, 1993). The Baseline Case and Future Case concentrations of manganese in sediment at the Gordon region are 737 mg/kg and 771 mg/kg, respectively. The Baseline Case and Future Case concentrations of manganese in sediment at the MacLellan region are 646 mg/kg and 658 mg/kg, respectively. As a comparison, sediment concentrations from 256 locations in the Great Lakes region of Ontario ranged from 30 mg/kg to 2,000 mg/kg (MOEE, 1993). The Baseline Case and Future Case concentrations are well within the ranges reported by the MOEE. Furthermore, the MOEE determined that the Lowest Effect Level (LEL) for benthic organisms was 460 mg/kg, while the Severe Effect Level (SEL) was 1,100 mg/kg (MOEE, 1993). Using the LEL as a toxicity threshold, SR are calculated as follows: for the Gordon region a SR of 1.6 for the Baseline Case and a SR of 1.7 for the Future Case (change of 0.1); and for the MacLellan region a SR of 1.4 for the Baseline Case and a SR of 1.4 for the Future Case (change of less than 0.1). As the changes in SR between

Baseline Case and Future Case are less than 1.0 for both the Gordon and MacLellan regions, unacceptable levels of risk to benthic invertebrates from exposure to manganese in sediment as a result of Project-related activities are not expected.

The increase in the concentration of strontium in sediment as a result of Project-related activities is 165% for the Gordon region and 9% for the MacLellan region. Strontium is a natural and commonly occurring element (ATSDR 2004). Strontium is a component of igneous rocks (average concentration of 375 mg/kg) and of various types of mineral deposits and is commonly associated with or near sedimentary rocks (ATSDR 2004). The Forum of European Geological Surveys collected stream bed sediment samples from nearly 900 stations across Europe to establish a global geochemical reference baseline concentration for various metals in sediment, including strontium. The median strontium concentration in stream sediments across Europe was 126 mg/kg, with a range from 31 to 1,352 mg/kg (Geochemical Atlas of Europe, 2006). Similarly, Environment Canada and Ministère du Développement durable, de l'Environnement et des Parcs du Québec (2007) collected sediment samples from the St. Lawrence to establish natural and ambient concentrations of various metals in sediment, including strontium. The 90th percentile was adapted to establish natural concentrations in pre-industrial sediment of 59 mg/kg and in postglacial clays of 110 mg/kg, while the 75th percentile was adapted to establish ambient concentrations in surficial sediment of three fluvial lakes, ranging from 320 to 400 mg/kg (EC and MDDEP 2007). Canadian Nuclear Laboratories (2018 and 2019) have also established background concentrations of several metals (and other chemicals) in sediment, including strontium. CNL (2018; 2019) have established a sediment upper limit background concentration of 370 mg/kg for strontium. Closer to the Gordon and MacLellan regions, sediment quality was assessed at various watercourses/lakes in Saskatchewan and Manitoba. Concentrations of strontium in these sediments ranged from 4 to 110 mg/kg (Stantec 2009). The Baseline Case and Future Case concentrations of strontium in sediment at the Gordon region is 31.1 mg/kg and 82.4 mg/kg, respectively. The Baseline Case and Future Case concentrations of strontium in sediment at the MacLellan region is 34.7 mg/kg and 37.8 mg/kg, respectively. These concentrations are within the typical concentration ranges observed for various waterbodies throughout Europe and Canada. Therefore, unacceptable risks to benthic invertebrates from exposure to strontium in sediments are not expected.

The increase in the concentration of thallium in sediment as a result of Project-related activities is 10% for the Gordon region and 2% for the MacLellan region. Thallium is ubiquitous in nature and is found especially in sulphide ores (van Vlaardingen et al. 2005). Thallium concentrations in surface and subsurface sediments at four remote Rocky Mountain National Park lakes, ranged from 0.13 to 0.27 mg/kg and from 0.14 to 0.30 mg/kg, respectively. Higher thallium concentrations (5.8 to 10.0 mg/kg) were observed in sediments from two Adirondack lakes (CCME, 1999e). The Baseline Case and Future Case concentrations of thallium in sediment at the Gordon region is 0.24 and 0.27 mg/kg respectively. The Baseline Case and Future Case concentrations of thallium in sediment at the MacLellan region is 0.189 and 0.192 mg/kg respectively. These concentrations are within the natural thallium concentrations in freshwater sediments as reported by CCME (1999e). Furthermore, van Vlaardingen et al. (2005) derived a maximum permissible concentration (MPC) in sediment, which represents the concentration that protects all species in the ecosystem from adverse effects of 1.2 mg/kg. Concentrations of thallium in sediment at the Gordon and MacLellan regions under both Baseline and Future Case are well below the MPC reported by van Vlaardingen et al. (2005). Using the MPC as a toxicity threshold, SR are calculated as follows: for the

Gordon region a SR of 0.20 for the Baseline Case and a SR of 0.23 for the Future Case (change of less than 0.1); and for the MacLellan region a SR of 0.16 for the Baseline Case and a SR of 0.16 for the Future Case (change of less than 0.1). As the changes in SR between Baseline Case and Future Case are less than 1.0 for both the Gordon and MacLellan regions, unacceptable levels of risk to benthic invertebrates from exposure to thallium in sediment as a result of Project-related activities are not expected.

The increase in the concentration of uranium in sediment as a result of Project-related activities is 25% for the Gordon region and 6% for the MacLellan region. Natural uranium concentrations in freshwater sediments are generally below 10 mg/kg; however, concentrations between 450 and 18,000 mg/kg have been measured near mining sites (CCME, 2011). The Baseline Case and Future Case concentrations of uranium in sediment at the Gordon region are 3.2 and 4.1 mg/kg respectively. The Baseline Case and Future Case concentrations of uranium in sediment at the MacLellan region are 1.6 and 1.7 mg/kg respectively. These concentrations are well within the natural uranium concentrations in freshwater sediment as reported by CCME (2011). Furthermore, Sheppard et al. (2005) derived a predicted no effect concentration (PNEC) for uranium toxicity for benthic organisms of 100 mg/kg. Concentrations of uranium in sediment at the Gordon and MacLellan regions are well below the PNEC reported by Sheppard et al. (2005). Using the PNEC as a toxicity threshold, SR are calculated as follows: for the Gordon region a SR of 0.032 for the Baseline Case and a SR of 0.041 for the Future Case (change of less than 0.1); and for the MacLellan region a SR of 0.016 for the Baseline Case and a SR of 0.017 for the Future Case (change of less than 0.1). As the changes in SR between Baseline Case and Future Case are less than 1.0 for both the Gordon and MacLellan regions, unacceptable levels of risk to benthic invertebrates from exposure to uranium in sediment as a result of Project-related activities are not expected.

” **---**"- not calculated because a toxicity benchmark was not available.

6.4.1.4 Freshwater Aquatic Communities

Screening ratios (SR) for freshwater aquatic communities (i.e., aquatic plants, aquatic invertebrates and fish) exposed to COPC in surface water were calculated by comparing surface water concentrations to freshwater aquatic life quality guidelines as outlined in Section 6.3.2. In cases where the benchmark was dependent on hardness, pH and/or dissolved organic carbon (DOC), conservative assumptions were used to derived site-specific guidelines, which include the use of the minimum measured hardness, the maximum measured pH and a DOC of 0.5 mg/L (default value as recommended by CCME). This was considered to be a conservative approach because anticipated Project-related increases in hardness and decreases in pH would result in higher, less conservative guideline values. DOC was conservatively assigned a value of 0.5 mg/L, which is well below the minimum observed value for DOC among baseline monitoring sites in the RAA.

The SRs for the Baseline Case and the Future Case, which are based on the freshwater aquatic life benchmarks provided in Appendix G, are provided in Table 6-37. The SRs for both the Baseline Case and the Future Case were below the threshold of 1.0, suggesting that Project-related activities are not anticipated to result in unacceptable health risks for freshwater aquatic communities.

An aquatic life toxicity benchmark was not identified for strontium; therefore, a SR was not calculated. However, inferences about the magnitude of risk for freshwater aquatic communities from exposure to strontium in surface water as a result of the project, can be made by looking at the difference in the water concentrations between Baseline Case and Future Case. The increase in the concentration of strontium in surface water as a result of Project-related activities is 84% for the Gordon region and 49% for the MacLellan region. Strontium is present in nearly all fresh waters in amounts generally ranging between 0.5 and 1.5 mg/L, with higher levels occurring where there are celestite-rich limestone deposits (ATSDR, 2004). Baseline concentrations of strontium in surface water at the Gordon and MacLellan regions were 0.09 mg/L and 0.02 mg/L, respectively. Future case concentrations of strontium in surface water at the Gordon and MacLellan regions were 0.17 and 0.02 mg/L, respectively. These concentrations are well within the strontium concentrations in freshwaters as reported by the ATSDR. Furthermore, Environment and Climate Change Canada (ECCC) has drafted a federal environmental quality guideline (FEQG) for strontium in freshwater for the protection of aquatic life of 1.7 mg/L (ECCC 2019). Also, the European Chemicals Agency (ECHA), an agency of the European Union (EU) that manages registration, evaluations, authorization, and restriction of chemicals within the EU, reports chronic NOECs for aquatic organisms that are greater than or equal to 21 mg/L (ECHA 2019). Again, concentrations of strontium in surface waters at the Gordon and MacLellan regions are well below the aquatic toxicity benchmarks drafted by ECCC and reported by the ECHA. Using the draft FEQG as a toxicity threshold, SR are calculated as follows: for the Gordon region a SR of 0.053 for the Baseline Case and a SR of 0.10 for the Future Case (change of less than 0.1); and for the MacLellan region a SR of 0.012 for the Baseline Case and a SR of 0.012 for the Future Case (change of less than 0.1). As the changes in SR between Baseline Case and Future Case are less than 1.0 for both the Gordon and MacLellan regions, unacceptable levels of risk to freshwater aquatic communities from exposure to strontium in surface water as a result of Project-related activities are not expected.

NOTES

[a] Benchmark was conservatively based on minimum measured water hardness of 10.9 mg/L $CaCO_3$ at the Gordon region and 4.5 mg/L $CaCO_3$ at the MacLellan region.

[b] Benchmark was conservatively based on maximum measured pH of 8.84 at the Gordon region and 8.94 at the MacLellan region.

[c] Benchmark was based on the default DOC value of 0.5 mg/L as recommended by CCME.

"---" not calculated because a toxicity benchmark was not available.

6.4.1.5 Herptiles

There is limited exposure and toxicity data to support the assessment of amphibians. Therefore, amphibians were evaluated qualitatively. Most amphibians require water for survival and reproduction. Early life stages of most amphibians live completely in permanent or temporary water bodies. Direct contact with surface water is one of the most important exposure pathways for early life stages because the skin of amphibians can absorb waterborne contaminants. Sediment and sediment porewater are also major exposure pathways for early amphibian life stages as well as for mature life stages. Some amphibian species deposit their embryos directly in sediment. Once hatched, the larvae can forage in sediment and are thus exposed to contaminants through direct contact and incidental ingestion. When amphibians complete metamorphosis, they reside mostly in the terrestrial environment. Direct contact with soil is a major exposure pathway for adults because some amphibians bury themselves in soil to stay moist during dry seasons or hibernate in the soil during winter. Amphibians also absorb much of the water in the soil through their skin as a way to remain hydrated in the terrestrial environment; thus, dermal uptake of dissolved contaminants from soil porewater is a significant exposure pathway. Adult amphibians rarely ingest water, except under extremely dry conditions (FCSAP, 2019).

Dietary information on amphibians is extremely limited and food and water intake rates are unknown. Most amphibian larvae are herbivorous, but a few species become omnivorous. Most amphibian adults are carnivorous, feeding on a variety of aquatic and terrestrial invertebrates, fish and other amphibians, and occasionally on small mammals, such as mice and birds (FCSAP, 2019).

The most sensitive life stage for amphibians is the tadpole stage, during which the amphibian is immersed in water. As such, fish may be a suitable surrogate for amphibian exposure. Aquatic receptors were evaluated in Section 6.4.1.4 and risks to fish and freshwater aquatic life from the construction and operation of the Project were acceptable. Thus, unacceptable risks to amphibians are not anticipated either.

Reptiles (e.g., turtles and snakes) are not expected to occur in the RAA and thus were not included in this assessment.

6.5 UNCERTAINTY ANALYSIS

6.5.1 Modelling Techniques

This ERA was conducted according to accepted risk assessment methodologies and follows guidance published and endorsed by regulatory agencies such as the CCME and the FCSAP. This approach is consistent with previous projects that have been reviewed by the Canadian Environmental Assessment Agency (CEAA). Risk estimates were derived through the inclusion of baseline data from multiple media (soil, water, tissue), modelling techniques following federal ERA guidance (CCME 1996, 2020; FCSAP 2012) for the prediction of Future Case concentrations as well as Baseline Case concentrations for parameters/media not measured, information about likely species of interest through engagement of local Indigenous communities and professional judgement. ERAs have inherent uncertainty related to the assumptions applied in the risk calculations. This uncertainty is often the result of conservative assumptions aimed at overestimating predictions of risks. This section provides more details on the nature of the uncertainties and the conservative approach that was used.

6.5.2 Modelling Scenario

There are uncertainties inherent to all types of predictive modelling techniques. There are uncertainties associated with data inputs that are modelled independently of the ERA (i.e., deposition, surface water and sediment quality modelling). These data inputs introduce uncertainties that are independent of the ERA process, but affect the final risk estimate to ecological receptors. Differences between modelled and actual Future Case conditions for climate, wind, weather and project influences may result in uncertainties. As part of the conservative approach to risk assessments, the worst-case modelling conditions are typically selected for application into the ERA.

6.5.3 Receptor Selection

The ecological receptors that were selected are known to be present, or can reasonably be expected to be present, near the Project, either at the Gordon region, the MacLellan region or both. These receptors are also suitable surrogates for other species that may be present, including species at risk. The use of site-specific receptors decreases the uncertainty in the assessment.

6.5.4 Use of Ecological Receptors to Represent Other Organisms

The use of receptors as sentinels is intended to limit the number of ecological receptors evaluated. The receptors selected are considered to be sensitive, regularly present at or near the Project, and to be exposed to the COPC via relevant exposure pathways. Therefore, it is reasonable to assume that conclusions that are reached in respect of the modelled receptor organisms can be generalized to other biota that might use the region near the Project.

6.5.5 Receptor-Specific Toxicity Data

For most COPC and receptors, toxicity data are available in some form. However, toxicity data are not necessarily available for the particular receptor species under consideration (e.g., black bear), or to a reproductive or population-level endpoint. As a result, there is uncertainty associated with the extrapolations that may be used to translate toxicity data for one species into a TRV for a second species. The toxicity data represent an organism or organisms that are expected to be sensitive to the COPC. The conversion factors that are used are scientifically based and are applied in a reasonable manner.

6.5.6 Food Chain Interactions

Very limited "real world" data exist that allow quantification of the true relationship between a COPC in an environmental medium and chemical transfer through the food chain. Only a few classes of chemicals (excluding metals) appear to be magnified through the food chain. The extent of food chain magnification is another uncertainty that is generally treated in a conservative manner. Baseline concentrations of trace metals in a wide variety of environmental media and food items were measured, including soil, surface water, sediment, small mammals, fish, forage, browse, and berries. Future concentrations of trace metals in these environmental media and food items were predicted using methods and models that are considered to be realistic and/or conservative.

6.5.7 Wildlife Exposure Factors

Most factors incorporated into dose calculations for ecological receptor species possess a site-specific component. Validity of each exposure factor is dependent on consideration of the site-specific nature of these factors. In the absence of site-specific validation, exposure factors are incorporated based on validations performed elsewhere for other cases and sometimes for other species. Considerations such as food ingestion rates, water ingestion rates, incidental soil ingestion rates, dietary composition, home range, and time spent near the Project were collected from the scientific literature based on other sites and locations.

6.5.8 Measurement Endpoints from the Toxicity Data

The limited amount of toxicity data available for many chemicals restricted the measurement endpoints that were available. Given the overall tendency to introduce conservatism (through the use of data or assumptions that are likely to overstate, rather than understate risk) into risk assessments, it is highly likely that no adverse environmental effect will exist below the RQ (or SR) target value of less than 1.0. However, an RQ (or SR) value greater than 1.0 is not by itself an indication that harm to receptor organisms will occur. The conservatisms inherent in the model development mitigate this conclusion, and the movements of wildlife receptors and consequent risk-averaging tend to reduce their actual exposure level in comparison with the exposure level predicted at point locations.

6.5.9 Exposure Assumptions

Generally, uncertainties are addressed by incorporating conservative assumptions (i.e., assumptions that are likely to overstate risk) in the analysis. Where several conservative assumptions are involved in the same calculation, a high level of conservatism can result from the combination of the assumptions. As a result, risk assessments tend to overstate the actual risk with the result that conclusions are robust. Although many factors are considered in preparation of a risk assessment, the results are generally most sensitive to a few key assumptions. Some of these modelling assumptions related to exposures include:

- The uptake rate of COPC from ingestion and dermal exposure to environmental media is assumed to be 100% (i.e., AF = 1.0).
- Ecological receptors are assumed to spend their entire lifetime in the area that could be affected by the Project.
- For the Baseline Case, ecological receptors were assumed to be exposed to measured concentrations of COPC in baseline environmental media based upon the 95% UCLM or maximum concentrations (soil, sediment, surface water, small mammals, fish, terrestrial plants).
- For the Future Case, ecological receptors were assumed to be exposed to predicted concentrations of COPC in environmental media based upon the 95% UCLM (soil, sediment, surface water, small mammals, fish, terrestrial plants).
- Ecological receptors were assumed to be exposed to 95% UCLM or maximum concentrations in environmental media regardless of their relative geographical proximity (e.g., surface water and sediment concentrations may be at distance from soil concentrations).
- Predicted concentrations of COPC in sediment are based on site-adjusted partitioning factors between surface water and sediment. Predicted concentrations of COPC in other media are also based on site-adjusted partitioning factors.
- Predicted concentrations of COPC in biota are based on exposure to COPC in environmental media. Biota are assumed to have been exposed to concentrations in environmental media long enough for their tissues to equilibrate with the surrounding media. For example, predicted concentrations of COPC in fish are based on exposure to COPC in the water column. Fish are assumed to have been exposed to these concentrations long enough for their tissues to equilibrate with the surrounding water.

6.5.10 Chemical Interactions from Multiple COPC

Ecological receptors are exposed to multiple COPC in the environment. The chemical interaction between multiple COPC or modifying factors (e.g., pH or water hardness) may result in additive, synergistic or antagonistic effects that are not distinguishable when evaluating the toxicity of COPC individually. Similar to the situation for human health, there is only a weak scientific understanding of the interaction and effects of multiple COPC and related modifying factors. Due to the lack of scientific evidence and approved assessment tools associated with modelling chemical interactions, these interactions were not evaluated in the ERA. However, this does not make the ERA non-conservative. Both interactions and modifying factors can influence the evaluation of potential risk. However, one of the main goals of the ERA is to conservatively assess potential risks by adopting numerous conservative biases in the risk assessment approach, such as using a maximum or 95% UCLM to represent the concentration over the entire area and using the most sensitive endpoint for the most sensitive species to represent the potential dose-response for all species within the study area. Efforts are made to err on the side of caution, providing a conservative level of risk without being unreasonable.

6.5.11 Summary of Uncertainties

A summary of the important assumptions and uncertainties in the ERA and the implications of these assumptions on risk estimates is provided in Table 6-38.

6.6 ERA SUMMARY

In general, Project-related contributions of COPC are not expected to result in unacceptable levels of risk to birds and mammals based on a comparison of RQs to a threshold of 1.0. In some cases RQs exceed the threshold of 1.0 in both the Baseline Case and the Future Case, with potential Future Case risks driven largely by baseline exposures to COPC. However, the differences between RQs for the Baseline Case and the Future Case were less than 1.0 for all COPC and all ecological receptors assessed at both the Gordon region and the MacLellan region, suggesting that the Project-related risks for ecological receptors are expected to be negligible.

The SRs for freshwater aquatic life communities were less than 1.0 for both the Baseline Case and the Future Case. The SRs for benthic communities, terrestrial plant and soil invertebrate communities were generally below 1.0. In some cases the SRs exceeded for both the Baseline Case and the Future Case. However, the changes between the Baseline Case and the Future Case SRs were less than 1.0 for all COPC and communities assesed at both the Gordon region and the MacLellan region indicating that Project-related risks for community receptors are expected to be negligible.

Table 6-34 Evaluation of Assumptions and Uncertainties Applied in the ERA

Assumptions/Uncertainty	Discussion of Conservatism	Analysis Likely to Overestimate/ Underestimate Risk
Modelling Techniques	Risk estimates were derived using modelling techniques based on federal ERA guidance (CCME 1996, 2020; FCSAP 2012) for the prediction of Future Case concentrations as well as Baseline Case concentrations for parameters/media not measured.	Neutral
Modelling Scenario	As part of the conservative approach to risk assessments, the worst-case modelling conditions were selected for application into the ERA. Ecological receptors were assumed to be exposed to potential upper limit exposures for each media at each region, regardless of specific locations of these concentrations. This approach is conservative as ecological receptors would be expected to move around at the site and not necessarily be exposed to the highest concentrations at the same location.	Overestimate
Receptor Selection	The ecological receptors that were selected are known to be present, or can reasonably be expected to be present, near the Project, either at the Gordon region, the MacLellan region or both.	Neutral
Using Receptors as Sentinels for other Organisms	The receptors selected are considered to be sensitive, regularly present at or near the Project, and to be exposed to the COPC via relevant exposure pathways.	Neutral
Receptor-Specific Toxicity Data	The toxicity data represent an organism or organisms that are expected to be sensitive to the COPC. The conversion factors that are used are scientifically based and are applied in a reasonable manner. This approach is considered conservative as selected receptors may be similarly or less sensitive.	Overestimate
Food Chain Interactions	Baseline concentrations of trace metals in a wide variety of environmental media and food items were measured, including soil, surface water, sediment, small mammals, fish, forage, browse, and berries. Future concentrations of trace metals in these environmental media and food items were predicted using methods and models that are considered to be realistic and/or conservative.	Neutral
Wildlife Exposure Factors	Most factors incorporated into dose calculations for ecological receptor species possess a site-specific component. In the absence of site-specific validation, exposure factors are incorporated based on validations performed elsewhere for other cases and sometimes for other species.	Neutral
Exposure Assumptions	The uptake rate of COPC from ingestion and direct exposure to environmental media is assumed to be 100% (i.e., AF = 1.0). This approach is conservative as COPC may not be 100% bioavailable in the environmental media and may not be expected to be completely uptaken through the gut and direct exposure.	Overestimate

Table 6-34 Evaluation of Assumptions and Uncertainties Applied in the ERA

Assumptions/Uncertainty	Discussion of Conservatism	Analysis Likely to Overestimate/ Underestimate Risk
Exposure Assumptions	Ecological receptors are assumed to spend their entire lifetime in the area that could be affected by the Project. This approach is conservative as some receptors may not spend 100% of their time in the areas of highest concentrations within the Gordon or MacLellan region (i.e., their foraging/home ranges may extend beyond the area that could be affected by the Project).	Overestimate
	Ecological receptors were assumed to be exposed to measured/predicted concentrations of COPC in environmental media (e.g., soil, sediment, surface water, small mammals, fish, terrestrial plants) based upon the 95% UCLM or maximum concentrations. The 95% UCLM is a conservative upper level estimate of the mean of concentrations at each region. The use of the 95% UCLM or maximum concentrations represents a conservative approach, as the concentrations in the food items ingested by mammals and birds would likely be at a lower concentration.	Overestimate
	Ecological receptors were assumed to be exposed to 95% UCLM or maximum concentrations in environmental media regardless of their relative geographical proximity (e.g., surface water and sediment concentrations may be at distance from soil concentrations). This approach is conservative as ecological receptors would be expected to move around at the site and not necessarily be exposed to the highest concentrations in each medium at the same time or location.	Overestimate
	Predicted concentrations of COPC in sediment are based on site-adjusted partitioning factors between surface water and sediment. Predicted concentrations of COPC in other media are also based on site-adjusted partitioning factors.	Neutral
	Predicted concentrations of COPC in biota are based on exposure to COPC in environmental media. Biota are assumed to have been exposed to concentrations in environmental media long enough for their tissues to equilibrate with the surrounding media. For example, predicted concentrations of COPC in fish are based on exposure to COPC in the water column. Fish are assumed to have been exposed to these concentrations long enough for their tissues to equilibrate with the surrounding water.	Neutral
Chemical Interactions from Multiple COPC	The chemical interaction between multiple COPC and modifying factors (e.g., pH or water hardness) may result in additive, synergistic or antagonistic effects that are not distinguishable when evaluating the toxicity of COPC individually. Due to the lack of scientific evidence and approved assessment tools associated with modelling chemical interactions, these interactions were not evaluated in the ERA.	Neutral

8.0 STANTEC QUALITY MANAGEMENT PROGRAM

This report, **Human Health and Ecological Risk Assessment Technical Modeling Report,** prepared for Alamos Gold Inc., dated April 30, 2020, was produced by Stantec Consulting Ltd.

This report was written by the following individuals:

Tony McKnight-Whitford, Ph.D.
Risk Assessor

Signature

Bryan Leece, Ph.D.
Senior Toxicologist

Signature

This report was reviewed by the following individuals:

Tania Noble, M.Eng., P. Eng.
Senior Principal

Signature

Loren Knopper, Ph.D.
Principal

Signature

Approval to transmit to client:

Karen Mathers, M.Sc., P.Geo. FGC, PMP
Senior Project Manager

Signature

This report was independently reviewed by Jennifer McPhail, M.Eng., P.Eng., Associate.

9.0 LIMITATIONS

This Technical Modelling Report entitled Lynn Lake Gold Project Human Health and Ecological Risk Assessment was prepared by Stantec Consulting Ltd. (“Stantec”) for the account of Alamos Gold Inc. (the “Client”) to support the approvals and permitting process from the Lynn Lake Gold Project in Lynn Lake, Manitoba. In connection thereto, this document may be reviewed and used by the federal and provincial government agencies participating in the approvals and permitting process in the normal course of their duties; and stakeholders may provide comment as part of the regulatory approvals process. Except as set forth in the previous sentence, any reliance on this document by any third party for any other purpose is strictly prohibited. The material in it reflects Stantec’s professional judgement in light of the scope, schedule and other limitations stated in the document and in the contract between Stantec and the Client. The opinions in contents of the document are based on conditions and information existing at the time the document was published and do not take into account any subsequent changes. In preparing the document, Stantec did not verify information supplied to it by others. Any unauthorized use that a third party makes of this document is the responsibility of such third part. Such third party agrees that Stantec shall not be responsible for costs or damages of any kind, if any, suffered by it or any other third party as a result of decisions made or actions taken based on unauthorized use of this document.

Suggested UCL to Use			
95% Student's-t UCL	1.1804E-8	or 95% Modified-t UCL	1.2069E-8

Note: Suggestions regarding the selection of a 95% UCL are provided to help the user to select the most appropriate 95% UCL.
Recommendations are based upon data size, data distribution, and skewness.
These recommendations are based upon the results of the simulation studies summarized in Singh, Maichle, and Lee (2006).
However, simulations results will not cover all Real World data sets; for additional insight the user may want to consult a statistician.

APPENDIX C.2
PROUCL OUTPUTS

Theta hat (MLE)	0.00389	Theta star (bias corrected MLE)	0.0062
nu hat (MLE)	498.4	nu star (bias corrected)	312.8

Mean (detects)	0.121		
Gamma ROS Statistics using Imputed Non-Detects			
GROS may not be used when data set has > 50% NDs with many tied observations at multiple DLs			
GROS may not be used when kstar of detects is small such as <1.0, especially when the sample size is small (e.g., <15-20)			
For such situations, GROS method may yield incorrect values of UCLs and BTVs			
This is especially true when the sample size is small.			
For gamma distributed detected data, BTVs and UCLs may be computed using gamma distribution on KM estimates			
Minimum	0.01	Mean	0.0668
Maximum	0.18	Median	0.0619
SD	0.0429	CV	0.642
k hat (MLE)	2.031	k star (bias corrected MLE)	1.837

When a data set follows an approximate (e.g., normal) distribution passing one of the GOF test			
When applicable, it is suggested to use a UCL based upon a distribution (e.g., gamma) passing both GOF tests in ProUCL			
Note: Suggestions regarding the selection of a 95% UCL are provided to help the user to select the most appropriate 95% UCL.			
Recommendations are based upon data size, data distribution, and skewness.			
These recommendations are based upon the results of the simulation studies summarized in Singh, Maichle, and Lee (2006).			
However, simulations results will not cover all Real World data sets; for additional insight the user may want to consult a statistician.

Note: Suggestions regarding the selection of a 95% UCL are provided to help the user to select the most appropriate 95% UCL.			
Recommendations are based upon data size, data distribution, and skewness.			
These recommendations are based upon the results of the simulation studies summarized in Singh, Maichle, and Lee (2006).			
However, simulations results will not cover all Real World data sets; for additional insight the user may want to consult a statistician.			
ProUCL computes and outputs H-statistic based UCLs for historical reasons only.			
H-statistic often results in unstable (both high and low) values of UCL95 as shown in examples in the Technical Guide.			
It is therefore recommended to avoid the use of H-statistic based 95% UCLs.			
Use of nonparametric methods are preferred to compute UCL95 for skewed data sets which do not follow a gamma distribution.

Gamma ROS Statistics using Imputed Non-Detects			
GROS may not be used when data set has > 50% NDs with many tied observations at multiple DLs			
GROS may not be used when kstar of detects is small such as <1.0, especially when the sample size is small (e.g., <15-20)			
For such situations, GROS method may yield incorrect values of UCLs and BTVs			
This is especially true when the sample size is small.			
For gamma distributed detected data, BTVs and UCLs may be computed using gamma distribution on KM estimates

Note: Suggestions regarding the selection of a 95% UCL are provided to help the user to select the most appropriate 95% UCL.			
Recommendations are based upon data size, data distribution, and skewness.			
These recommendations are based upon the results of the simulation studies summarized in Singh, Maichle, and Lee (2006).			
However, simulations results will not cover all Real World data sets; for additional insight the user may want to consult a statistician.			
ProUCL computes and outputs H-statistic based UCLs for historical reasons only.			
H-statistic often results in unstable (both high and low) values of UCL95 as shown in examples in the Technical Guide.			
It is therefore recommended to avoid the use of H-statistic based 95% UCLs.			
Use of nonparametric methods are preferred to compute UCL95 for skewed data sets which do not follow a gamma distribution.

Gamma ROS Statistics using Imputed Non-Detects			
GROS may not be used when data set has > 50% NDs with many tied observations at multiple DLs			
GROS may not be used when kstar of detects is small such as <1.0, especially when the sample size is small (e.g., <15-20)			
For such situations, GROS method may yield incorrect values of UCLs and BTVs			
This is especially true when the sample size is small.			
For gamma distributed detected data, BTVs and UCLs may be computed using gamma distribution on KM estimates

Nonparametric Distribution Free UCL Statistics			
Detected Data appear Approximate Gamma Distributed at 5% Significance Level			
Suggested UCL to Use			
95% KM Adjusted Gamma UCL	40.34	95% GROS Adjusted Gamma UCL	46.7
When a data set follows an approximate (e.g., normal) distribution passing one of the GOF test			
When applicable, it is suggested to use a UCL based upon a distribution (e.g., gamma) passing both GOF tests in ProUCL			
Note: Suggestions regarding the selection of a 95% UCL are provided to help the user to select the most appropriate 95% UCL.			
Recommendations are based upon data size, data distribution, and skewness.			
These recommendations are based upon the results of the simulation studies summarized in Singh, Maichle, and Lee (2006).			
However, simulations results will not cover all Real World data sets; for additional insight the user may want to consult a statistician.

97.5% KM Chebyshev UCL	0.153	99% KM Chebyshev UCL	0.175

Gamma GOF Tests on Detected Observations Only			
A-D Test Statistic	0.342	**Anderson-Darling GOF Test**	
5% A-D Critical Value	0.721	Detected data appear Gamma Distributed at 5% Significance Level	
K-S Test Statistic	0.187	**Kolmogorov-Smirnov GOF**	
5% K-S Critical Value	0.279	Detected data appear Gamma Distributed at 5% Significance Level	
Detected data appear Gamma Distributed at 5% Significance Level			

Gamma Statistics on Detected Data Only			
k hat (MLE)	16.94	k star (bias corrected MLE)	11.37
Theta hat (MLE)	0.00833	Theta star (bias corrected MLE)	0.0124
nu hat (MLE)	304.9	nu star (bias corrected)	204.6

Mean (detects)	0.141		
Gamma ROS Statistics using Imputed Non-Detects			
GROS may not be used when data set has > 50% NDs with many tied observations at multiple DLs			
GROS may not be used when kstar of detects is small such as <1.0, especially when the sample size is small (e.g., <15-20)			
For such situations, GROS method may yield incorrect values of UCLs and BTVs			
This is especially true when the sample size is small.			
For gamma distributed detected data, BTVs and UCLs may be computed using gamma distribution on KM estimates			
Minimum	0.01	Mean	0.0753
Maximum	0.21	Median	0.0642
SD	0.0586	CV	0.778
k hat (MLE)	1.383	k star (bias corrected MLE)	1.244
Theta hat (MLE)	0.0545	Theta star (bias corrected MLE)	0.0605
nu hat (MLE)	69.16	nu star (bias corrected)	62.19
Adjusted Level of Significance (β)	0.0395

Gamma ROS Statistics using Imputed Non-Detects			
GROS may not be used when data set has > 50% NDs with many tied observations at multiple DLs			
GROS may not be used when kstar of detects is small such as <1.0, especially when the sample size is small (e.g., <15-20)			
For such situations, GROS method may yield incorrect values of UCLs and BTVs			
This is especially true when the sample size is small.			
For gamma distributed detected data, BTVs and UCLs may be computed using gamma distribution on KM estimates

Detected Data appear Approximate Normal Distributed at 5% Significance Level			
Suggested UCL to Use			
95% KM (t) UCL	0.351		
When a data set follows an approximate (e.g., normal) distribution passing one of the GOF test			
When applicable, it is suggested to use a UCL based upon a distribution (e.g., gamma) passing both GOF tests in ProUCL			
Note: Suggestions regarding the selection of a 95% UCL are provided to help the user to select the most appropriate 95% UCL.			
Recommendations are based upon data size, data distribution, and skewness.			
These recommendations are based upon the results of the simulation studies summarized in Singh, Maichle, and Lee (2006).			
However, simulations results will not cover all Real World data sets; for additional insight the user may want to consult a statistician.

Suggested UCL to Use			
95% H-UCL	6.76		
Note: Suggestions regarding the selection of a 95% UCL are provided to help the user to select the most appropriate 95% UCL.			
Recommendations are based upon data size, data distribution, and skewness.			
These recommendations are based upon the results of the simulation studies summarized in Singh, Maichle, and Lee (2006).			
However, simulations results will not cover all Real World data sets; for additional insight the user may want to consult a statistician.			
ProUCL computes and outputs H-statistic based UCLs for historical reasons only.			
H-statistic often results in unstable (both high and low) values of UCL95 as shown in examples in the Technical Guide.			
It is therefore recommended to avoid the use of H-statistic based 95% UCLs.			
Use of nonparametric methods are preferred to compute UCL95 for skewed data sets which do not follow a gamma distribution.

Maximum Detect	0.41	Maximum Non-Detect	0.1
Variance Detects	0.00714	Percent Non-Detects	20%
Mean Detects	0.24	SD Detects	0.0845
Median Detects	0.22	CV Detects	0.352
Skewness Detects	1.397	Kurtosis Detects	1.469
Mean of Logged Detects	-1.474	SD of Logged Detects	0.318

Normal GOF Test on Detects Only		
Shapiro Wilk Test Statistic	0.847	**Shapiro Wilk GOF Test**
5% Shapiro Wilk Critical Value	0.818	Detected Data appear Normal at 5% Significance Level
Lilliefors Test Statistic	0.297	**Lilliefors GOF Test**
5% Lilliefors Critical Value	0.283	Detected Data Not Normal at 5% Significance Level
Detected Data appear Approximate Normal at 5% Significance Level		

Kaplan-Meier (KM) Statistics using Normal Critical Values and other Nonparametric UCLs			
KM Mean	0.212	KM Standard Error of Mean	0.0305
KM SD	0.0902	95% KM (BCA) UCL	0.258
95% KM (t) UCL	0.268	95% KM (Percentile Bootstrap) UCL	0.257
95% KM (z) UCL	0.262	95% KM Bootstrap t UCL	0.287
90% KM Chebyshev UCL	0.303	95% KM Chebyshev UCL	0.345
97.5% KM Chebyshev UCL	0.402	99% KM Chebyshev UCL	0.515

Gamma GOF Tests on Detected Observations Only		
A-D Test Statistic	0.463	**Anderson-Darling GOF Test**
5% A-D Critical Value	0.715	Detected data appear Gamma Distributed at 5% Significance Level
K-S Test Statistic	0.265	**Kolmogorov-Smirnov GOF**
5% K-S Critical Value	0.294	Detected data appear Gamma Distributed at 5% Significance Level
Detected data appear Gamma Distributed at 5% Significance Level		

Gamma Statistics on Detected Data Only			
k hat (MLE)	10.77	k star (bias corrected MLE)	6.812
Theta hat (MLE)	0.0223	Theta star (bias corrected MLE)	0.0352
nu hat (MLE)	172.2	nu star (bias corrected)	109

Mean (detects)	0.24		
Gamma ROS Statistics using Imputed Non-Detects			
GROS may not be used when data set has > 50% NDs with many tied observations at multiple DLs			
GROS may not be used when kstar of detects is small such as <1.0, especially when the sample size is small (e.g., <15-20)			
For such situations, GROS method may yield incorrect values of UCLs and BTVs			
This is especially true when the sample size is small.			
For gamma distributed detected data, BTVs and UCLs may be computed using gamma distribution on KM estimates			
Minimum	0.0501	Mean	0.205
Maximum	0.41	Median	0.205
SD	0.105	CV	0.509
k hat (MLE)	3.635	k star (bias corrected MLE)	2.611
Theta hat (MLE)	0.0565	Theta star (bias corrected MLE)	0.0787
nu hat (MLE)	72.69	nu star (bias corrected)	52.22
Adjusted Level of Significance (β)	0.0267		
Approximate Chi Square Value (52.22, α)	36.62	Adjusted Chi Square Value (52.22, β)	34.36
95% Gamma Approximate UCL (use when n>=50)	0.293	95% Gamma Adjusted UCL (use when n<50)	0.312
Estimates of Gamma Parameters using KM Estimates			
Mean (KM)	0.212	SD (KM)	0.0902

Suggested UCL to Use			
95% Student's-t UCL	0.417		
When a data set follows an approximate (e.g., normal) distribution passing one of the GOF test			
When applicable, it is suggested to use a UCL based upon a distribution (e.g., gamma) passing both GOF tests in ProUCL			
Note: Suggestions regarding the selection of a 95% UCL are provided to help the user to select the most appropriate 95% UCL.			
Recommendations are based upon data size, data distribution, and skewness.			
These recommendations are based upon the results of the simulation studies summarized in Singh, Maichle, and Lee (2006).			
However, simulations results will not cover all Real World data sets; for additional insight the user may want to consult a statistician.			
Note: For highly negatively-skewed data, confidence limits (e.g., Chen, Johnson, Lognormal, and Gamma) may not be			
reliable. Chen's and Johnson's methods provide adjustments for positvely skewed data sets.

Gamma ROS Statistics using Imputed Non-Detects			
GROS may not be used when data set has > 50% NDs with many tied observations at multiple DLs			
GROS may not be used when kstar of detects is small such as <1.0, especially when the sample size is small (e.g., <15-20)			
For such situations, GROS method may yield incorrect values of UCLs and BTVs			
This is especially true when the sample size is small.			
For gamma distributed detected data, BTVs and UCLs may be computed using gamma distribution on KM estimates

Note: Suggestions regarding the selection of a 95% UCL are provided to help the user to select the most appropriate 95% UCL.			
Recommendations are based upon data size, data distribution, and skewness.			
These recommendations are based upon the results of the simulation studies summarized in Singh, Maichle, and Lee (2006).			
However, simulations results will not cover all Real World data sets; for additional insight the user may want to consult a statistician.			
ProUCL computes and outputs H-statistic based UCLs for historical reasons only.			
H-statistic often results in unstable (both high and low) values of UCL95 as shown in examples in the Technical Guide.			
It is therefore recommended to avoid the use of H-statistic based 95% UCLs.			
Use of nonparametric methods are preferred to compute UCL95 for skewed data sets which do not follow a gamma distribution.

Theta hat (MLE)	1.959	Theta star (bias corrected MLE)	2.128
nu hat (MLE)	65.7	nu star (bias corrected)	60.46

Mean (detects)	2.145		
Gamma ROS Statistics using Imputed Non-Detects			
GROS may not be used when data set has > 50% NDs with many tied observations at multiple DLs			
GROS may not be used when kstar of detects is small such as <1.0, especially when the sample size is small (e.g., <15-20)			
For such situations, GROS method may yield incorrect values of UCLs and BTVs			
This is especially true when the sample size is small.			
For gamma distributed detected data, BTVs and UCLs may be computed using gamma distribution on KM estimates			
Minimum	0.01	Mean	1.893
Maximum	13.62	Median	1.591

When a data set follows an approximate (e.g., normal) distribution passing one of the GOF test			
When applicable, it is suggested to use a UCL based upon a distribution (e.g., gamma) passing both GOF tests in ProUCL			
Note: Suggestions regarding the selection of a 95% UCL are provided to help the user to select the most appropriate 95% UCL.			
Recommendations are based upon data size, data distribution, and skewness.			
These recommendations are based upon the results of the simulation studies summarized in Singh, Maichle, and Lee (2006).			
However, simulations results will not cover all Real World data sets; for additional insight the user may want to consult a statistician.

Mean (detects)	0.0307		
Gamma ROS Statistics using Imputed Non-Detects			
GROS may not be used when data set has > 50% NDs with many tied observations at multiple DLs			
GROS may not be used when kstar of detects is small such as <1.0, especially when the sample size is small (e.g., <15-20)			
For such situations, GROS method may yield incorrect values of UCLs and BTVs			
This is especially true when the sample size is small.			
For gamma distributed detected data, BTVs and UCLs may be computed using gamma distribution on KM estimates

These recommendations are based upon the results of the simulation studies summarized in Singh, Maichle, and Lee (2006).			
However, simulations results will not cover all Real World data sets; for additional insight the user may want to consult a statistician.			
ProUCL computes and outputs H-statistic based UCLs for historical reasons only.			
H-statistic often results in unstable (both high and low) values of UCL95 as shown in examples in the Technical Guide.			
It is therefore recommended to avoid the use of H-statistic based 95% UCLs.			
Use of nonparametric methods are preferred to compute UCL95 for skewed data sets which do not follow a gamma distribution.

Note: Suggestions regarding the selection of a 95% UCL are provided to help the user to select the most appropriate 95% UCL.			
Recommendations are based upon data size, data distribution, and skewness.			
These recommendations are based upon the results of the simulation studies summarized in Singh, Maichle, and Lee (2006).			
However, simulations results will not cover all Real World data sets; for additional insight the user may want to consult a statistician.			

APPENDIX C.7

BERRIES TISSUE
MACLELLAN REGION

UCL Statistics for Data Sets with Non-Detects	
User Selected Options	
Date/Time of Computation	ProUCL 5.112/6/2019 3:47:50 AM
From File	MacLellan Region, Tissue - Berries, Barium (Ba), mg_kg ww.xls
Full Precision	OFF
Confidence Coefficient	95%
Number of Bootstrap Operations	2000

MacLellan Region, Tissue - Berries, Barium (Ba), mg/kg ww

General Statistics			
Total Number of Observations	28	Number of Distinct Observations	28
Number of Detects	23	Number of Non-Detects	5
Number of Distinct Detects	23	Number of Distinct Non-Detects	5
Minimum Detect	0.0331	Minimum Non-Detect	0.0268
Maximum Detect	4.18	Maximum Non-Detect	0.0472
Variance Detects	1.111	Percent Non-Detects	17.86%
Mean Detects	2.004	SD Detects	1.054
Median Detects	2.295	CV Detects	0.526
Skewness Detects	-0.152	Kurtosis Detects	-0.405
Mean of Logged Detects	0.346	SD of Logged Detects	1.234

Normal GOF Test on Detects Only			
Shapiro Wilk Test Statistic	0.96	**Shapiro Wilk GOF Test**	
5% Shapiro Wilk Critical Value	0.914	Detected Data appear Normal at 5% Significance Level	
Lilliefors Test Statistic	0.146	**Lilliefors GOF Test**	
5% Lilliefors Critical Value	0.18	Detected Data appear Normal at 5% Significance Level	
Detected Data appear Normal at 5% Significance Level			

Kaplan-Meier (KM) Statistics using Normal Critical Values and other Nonparametric UCLs			
KM Mean	1.651	KM Standard Error of Mean	0.232
KM SD	1.203	95% KM (BCA) UCL	2.019
95% KM (t) UCL	2.047	95% KM (Percentile Bootstrap) UCL	2.023
95% KM (z) UCL	2.033	95% KM Bootstrap t UCL	2.054
90% KM Chebyshev UCL	2.348	95% KM Chebyshev UCL	2.664
97.5% KM Chebyshev UCL	3.102	99% KM Chebyshev UCL	3.963

Gamma GOF Tests on Detected Observations Only			
A-D Test Statistic	1.765	**Anderson-Darling GOF Test**	
5% A-D Critical Value	0.759	Detected Data Not Gamma Distributed at 5% Significance Level	
K-S Test Statistic	0.219	**Kolmogorov-Smirnov GOF**	
5% K-S Critical Value	0.185	Detected Data Not Gamma Distributed at 5% Significance Level	
Detected Data Not Gamma Distributed at 5% Significance Level			

Gamma Statistics on Detected Data Only			
k hat (MLE)	1.576	k star (bias corrected MLE)	1.4
Theta hat (MLE)	1.271	Theta star (bias corrected MLE)	1.432
nu hat (MLE)	72.51	nu star (bias corrected)	64.38

Mean (detects)	2.004		
Gamma ROS Statistics using Imputed Non-Detects			
GROS may not be used when data set has > 50% NDs with many tied observations at multiple DLs			
GROS may not be used when kstar of detects is small such as <1.0, especially when the sample size is small (e.g., <15-20)			
For such situations, GROS method may yield incorrect values of UCLs and BTVs			
This is especially true when the sample size is small.			
For gamma distributed detected data, BTVs and UCLs may be computed using gamma distribution on KM estimates			
Minimum	0.0331	Mean	1.755
Maximum	4.18	Median	1.437
SD	1.096	CV	0.624
k hat (MLE)	1.507	k star (bias corrected MLE)	1.369
Theta hat (MLE)	1.165	Theta star (bias corrected MLE)	1.282
nu hat (MLE)	84.4	nu star (bias corrected)	76.69
Adjusted Level of Significance (β)	0.0404		
Approximate Chi Square Value (76.69, α)	57.52	Adjusted Chi Square Value (76.69, β)	56.49
95% Gamma Approximate UCL (use when n>=50)	2.341	95% Gamma Adjusted UCL (use when n<50)	2.383
Estimates of Gamma Parameters using KM Estimates			
Mean (KM)	1.651	SD (KM)	1.203
Variance (KM)	1.446	SE of Mean (KM)	0.232
k hat (KM)	1.885	k star (KM)	1.707
nu hat (KM)	105.6	nu star (KM)	95.6
theta hat (KM)	0.876	theta star (KM)	0.967
80% gamma percentile (KM)	2.518	90% gamma percentile (KM)	3.335
95% gamma percentile (KM)	4.121	99% gamma percentile (KM)	5.883
Gamma Kaplan-Meier (KM) Statistics			
Approximate Chi Square Value (95.60, α)	74.05	Adjusted Chi Square Value (95.60, β)	72.88
95% Gamma Approximate KM-UCL (use when n>=50)	2.132	95% Gamma Adjusted KM-UCL (use when n<50)	2.166
Lognormal GOF Test on Detected Observations Only			
Shapiro Wilk Test Statistic	0.645	**Shapiro Wilk GOF Test**	
5% Shapiro Wilk Critical Value	0.914	Detected Data Not Lognormal at 5% Significance Level	
Lilliefors Test Statistic	0.266	**Lilliefors GOF Test**	
5% Lilliefors Critical Value	0.18	Detected Data Not Lognormal at 5% Significance Level	
Detected Data Not Lognormal at 5% Significance Level			
Lognormal ROS Statistics Using Imputed Non-Detects			
Mean in Original Scale	1.679	Mean in Log Scale	-0.0188
SD in Original Scale	1.187	SD in Log Scale	1.371
95% t UCL (assumes normality of ROS data)	2.061	95% Percentile Bootstrap UCL	2.047
95% BCA Bootstrap UCL	2.063	95% Bootstrap t UCL	2.076
95% H-UCL (Log ROS)	5.459		
Statistics using KM estimates on Logged Data and Assuming Lognormal Distribution			
KM Mean (logged)	-0.357	KM Geo Mean	0.7
KM SD (logged)	1.862	95% Critical H Value (KM-Log)	3.672
KM Standard Error of Mean (logged)	0.36	95% H-UCL (KM -Log)	14.77

KM SD (logged)	1.862	95% Critical H Value (KM-Log)	3.672
KM Standard Error of Mean (logged)	0.36		
DL/2 Statistics			
DL/2 Normal		DL/2 Log-Transformed	
Mean in Original Scale	1.649	Mean in Log Scale	-0.443
SD in Original Scale	1.227	SD in Log Scale	2.053
95% t UCL (Assumes normality)	2.044	95% H-Stat UCL	25.35
DL/2 is not a recommended method, provided for comparisons and historical reasons			
Nonparametric Distribution Free UCL Statistics			
Detected Data appear Normal Distributed at 5% Significance Level			
Suggested UCL to Use			
95% KM (t) UCL	2.047		
Note: Suggestions regarding the selection of a 95% UCL are provided to help the user to select the most appropriate 95% UCL.			
Recommendations are based upon data size, data distribution, and skewness.			
These recommendations are based upon the results of the simulation studies summarized in Singh, Maichle, and Lee (2006).			
However, simulations results will not cover all Real World data sets; for additional insight the user may want to consult a statistician.
